Rather than listing all the existing types of biomaterials used, we will deal only with some for which we have a firsthand experience to ensure the accuracy of the account. But these will nonetheless illustrate the basic principles involved as also put to use by other companies, which are sharing a worldwide market volume estimated in 2015 at 1 billion US\$ for fixed partial prostheses (FDPs), including all ceramic as well as metal ceramic restorations. Along with Ivoclar Vivadent, the main producers of materials widely used in clinical practice are VITA Zahnfabrik (Germany) with feldspathic, lithium silicate, and leucite-based systems, Dentsply Sirona (United States and Austria) and GC Corporation (Japan) with lithium silicate and leucite-based systems, and Kuraray Noritake Dental (Japan) with leucite-based systems.

2 History and Present Uses of Dental Glass-Ceramics

Since time immemorial patients whose teeth have been damaged by either caries or periodontal disease or by traumatic incidents and accidents have expressed a desire to have them repaired. In many cases, only part of a tooth has to be replaced so that the still functioning part can be maintained. Dental inlays, onlays, crowns, bridges, or veneers are used to repair such defects (Figure 1). In situations where a tooth has to be extracted completely and replaced, implants or dental bridges are indicated. These types of replacements have to mimic the appearance of the original tooth, which implies that their optical properties should match those of the natural counterparts, and assume all the masticatory functions of the structure. As a result, restorative materials must be as strong and tough as natural teeth, exhibit high or even unparalleled resistance to the oral environment, and demonstrate the same attrition as natural teeth to help protect the opposing teeth. Finally, it is desirable for the restorative material to have the same thermal properties and coefficient of thermal expansion as that of the natural dentition.

In addition to the needs of patients, the equally important requirements of dentists and dental technicians must be considered in the development of suitable dental restorative materials. For example, these include more economically efficient working methods, effective cementation techniques for bonding dental materials to natural tooth structure, and also the visibility of restorative materials in X-ray images (radiopacity).

The first glass-ceramics to incorporate a successful combination of optical and mechanical properties was

DICOR® (Corning Inc./Dentsply International, USA). The favorable properties of this material were achieved through the precipitation of tetrasilicic mica crystals, $\text{KMg}_{2.5}\text{Si}_4\text{O}_{10}\text{F}_2$ [6, 7]. Since this glass-ceramics featured a silica-rich glass matrix in addition to the crystals, it could be formed in the molten state and shaped into any desired dental restoration, for example, inlays, onlays, and crowns. The glass matrix also imparted the material with desirable optical and translucent properties. This constituted a major advantage over the previously known dental materials. Moreover, since mica crystals demonstrate eminent cleavage properties [1], this glass-ceramics could be machined in addition to being shaped with a hot-melt process.

Glass-ceramics as well as organic composite materials and inorganic sintered ceramics (e.g. ZrO_2 based) have become very popular because they allow particular properties to be combined selectively. Over time, the properties of the initial glass-ceramics have been further developed and improved, and new ones have been effectively combined. Nevertheless, finding the correct combination of mechanical parameters and optical and processing properties has posed a considerable challenge. In many cases, an increase in the mechanical properties, that is, strength and toughness, resulted in a decrease of light transmission properties, which made the materials look dull and opaque. In some cases, they showed inferior chemical durability compared with that of natural teeth. These types of weaknesses had to be overcome in ways satisfying the requirements described in detail in the next section.

3 Properties of Dental Glass-Ceramics

3.1 Mechanical Properties

The main mechanical properties that need to be addressed are wear resistance (established with a chewing simulator) and strength, measured as the biaxial flexural strength (according to ISO 6872), the K_{IC} value (according to single-edge V-notched beam [SEVNB] method). As already emphasized, it is important that the mechanical strength and toughness of dental biomaterials match the parameters of natural teeth. This constraint applies to the biomaterials used to fabricate dental inlays and, in some cases, to dental crowns in the anterior region. Other parameters must be observed in the development of dental biomaterials used to produce crowns for posterior teeth or abutments on implants or even dental bridges. The mechanical properties of these biomaterials should be significantly higher than those of natural teeth. Given these requirements, it is obvious that various types of glass-ceramics

Figure 1 Glass-ceramics for dental restoration. (a) Dental bridge, lithium disilicate glass-ceramics veneered with an apatite glass-ceramic: IPS e.max® type. (b)–(c) Leucite glass-ceramics of IPS Empress® type. (b) Crown. (c) Inlay. (d) Veneer. Products of Ivoclar Vivadent AG, Liechtenstein. Reproduced from [1] with permission from Wiley.

are needed for different applications, as is the case with metal or rather steel. For example, materials used to fabricate dental inlays or crowns should exhibit, according to ISO6872, strengths and K_{IC} values higher than 100 MPa and $1.0 \text{ MPa m}^{0.5}$, respectively. By comparison, the strength and K_{IC} values of materials for dental three-unit anterior bridges should be higher than 300 MPa and $2.0 \text{ MPa m}^{0.5}$. These values could be achieved with glass-ceramics of a high crystal content and an interlocking microstructure.

3.2 Optical Properties

The optical property of light transmission or translucency is measured according to the British Standard BS 5612. Translucency is compared against a reference and established as a dimensionless number between 0 (zero), i.e. 100% light transmission of white light, and 1.0, a value indicating that the material is opaque so that any light does not pass through it. A desirable translucency for materials used in restorative dentistry lies between 0.5 and 0.8, depending on whether the tooth is vital or devitalized or anterior or posterior. This can be controlled in dependence of the crystal content and the corresponding microstructure.

3.3 Thermal Properties

The most important thermal parameters for dental materials are the coefficient of linear thermal expansion (CTE) and the thermal shock resistance. The desirable CTE parameters are higher than $10 \times 10^{-6} \text{ K}^{-1}$ (100–400 °C). In clinical situations, a dental material has to be resistant to thermal shock at temperatures between 37 °C (normal body temperature) and 50 °C or so (hot beverages) or even in the negative Celsius range upon consumption of ice creams. This property is closely analyzed in *in vitro* tests, and the material is optimized accordingly in terms of the glass composition and the microstructure. Furthermore, the material is tested in the chewing simulator, where the wear resistance compared with that of natural teeth is examined and the resistance to thermal shock is studied.

The resistance to thermal shock of a material should be tested not only with regard to the conditions in the mouth but also to the processing procedures followed by the dentist and the dental technician. It is often necessary for a material to withstand rapid temperature changes over a range of $\pm 100 \text{ K}$. The optimization of thermal shock resistance is a result of CTE control via the design of the microstructure of the glass-ceramics.

3.4 Chemical Properties

Like mechanical and thermal properties, the chemical durability of biomaterials can be determined by means of *in vitro* investigations. It is of utmost importance for the materials to be resistant to the acidic oral environment. The ISO 6872 norm on dental ceramic materials specifies that chemical durability must be tested in dilute acetic acid [CH_3COOH]. The resistance is measured as a loss of mass in relation to the surface. Depending on the application of the biomaterials, e.g. as a substructure with veneer or a non-veneered material, different limiting values apply, which range between 10 and $100 \mu\text{g}/\text{cm}^2$ and 100 and $2000 \mu\text{g}/\text{cm}^2$, respectively.

The aforementioned parameters refer to those that need to be fulfilled in the mouth of the patient. At the same time, the material has to demonstrate some etchability. This allows it to be treated with an acid in order to obtain a retentive surface, which will strengthen the bond to the tooth. Glass-ceramics do fulfill these requirements.

3.5 Radiopacity

Because the dental restoration must match the optical properties of natural teeth, the biomaterial may be difficult to distinguish from the real tooth structure. This *chameleon effect* makes the margin of the preparation blend in with the natural dentition, which causes, therefore, any contrast to disappear. For dentists, however, the preparation margins should remain visible in case the restoration needs to be removed. One can do it by incorporating certain radiopaque properties into the material, for example, by precipitating in the glass-ceramic $\text{Sr}_5(\text{PO}_4)_3\text{F}$ instead of $\text{Ca}_5(\text{PO}_4)_3\text{F}$ and Cs-leucite [$\text{CsAlSi}_2\text{O}_6$] (see Section 5 and reference [8]). These phases thus make the material structure look different from that of natural teeth in X-ray images.

4 Examples of Dental Glass-Ceramics

4.1 Leucite-Based Glass-Ceramics

The glass-ceramic IPS Empress® (Ivoclar Vivadent AG, Liechtenstein) is a dental restorative biomaterial, which can be either molded or machined. Its main properties are summarized in Table 1. This glass-ceramics has a chemical composition in the range of 59–63 wt % SiO_2 , 19–23.5 Al_2O_3 , 10–14 K_2O , 2.3–6.5 Na_2O , 0–1 B_2O_3 , 0–1 CeO_2 , and 0.5–3 CaO . Tetragonal leucite crystals [KAlSi_2O_6] constitute the main crystal phase [1]. This framework aluminosilicate displays characteristic Q^4 ($\text{SiO}_{4/2}$ and $\text{AlO}_{4/2}^-$, cf. Chapter 2.4) structural units in

Table 1 Properties of IPS Empress® CAD (scientific report of November 2006, Ivoclar Vivadent AG) and IPS e.max® CAD (scientific report of March 2011, Ivoclar Vivadent AG).

	IPS Empress® CAD	IPS e.max® CAD
Biaxial flexural strength (MPa)	>160	>360
K_{IC} (MPa m ^{0.5})	1.3	>2.0
Translucency	0.4–0.7	0.4–0.8
Coefficient of thermal expansion (CTE) (10 ⁻⁶ /K)	17–18	10–11
Chemical durability (μg/cm ²)	<100	<50

its structure (Figure 2a). The growth of this crystal phase begins with a typical surface nucleation process, which is initiated at the surface of the glass grains through tribochemical activation. The subsequent nucleation process proceeds inward from the surface. For this manufacturing step, monolithic glass-ceramics are produced as powder compacts.

The processes of nucleation, crystallization, and simultaneous sintering that are involved in the manufacture of the final product are clearly very complex. The microstructure of this leucite glass-ceramics (Figure 2b) shows a typical characteristic of leucite crystals, that is, polysynthetic twinning [1]. All crystals show this twinning effect in their growth. Depending on the desired translucency level, the growth process, which is diffusion controlled, can be frozen in order to achieve the required properties, especially to control the high CTE.

The molding procedure is a very special Ivoclar Vivadent AG invention. Today, this technology is widely used also by other companies. In contrast to hot melting, the viscous flow takes place in a higher viscosity range and, thus, at lower temperatures. Because the viscosity of the material in this flow process is approximately 10¹¹ Pa-s, dental restorations such as inlays, onlays, and crowns can be fabricated with the lost-wax technique whereby the viscous ceramic is pressed into an individually created mold made of a special *investment material*. Thanks to these lower temperatures, reactions with the investment material are significantly reduced with this method compared with the hot-melt technique.

Surprisingly, the IPS Empress® glass-ceramics can also be machined, thanks to the microstructure of the glass-ceramics.

4.2 Lithium Disilicate Glass-Ceramics

The glass-ceramic IPS e.max® CAD and Press (Ivoclar Vivadent AG, Liechtenstein) was developed with the aim of producing a stronger material than IPS Empress® to be used to fabricate dental bridges and abutments. This was achieved through precipitation of high amounts of lithium disilicate crystals [Li₂Si₂O₅], whose structure is shown in Figure 3a. These glass-ceramic systems show a high nucleation and crystallization rate [1].

Although Li₂Si₂O₅ is a layer silicate, these crystals do not have any cleavage properties. Van der Waals forces are usually invoked for crystals such as graphite or talc for which they determine their very weak interplanar bonding. For other structures, cleavage and cleavage energy are determined by the planes of lowest

Figure 2 Leucite-based glass-ceramics used in IPS Empress®. ionic or covalent energy throughout the crystal; see, for example, [9].

In 1959, the first glass-ceramics was developed by Stookey in the form of a lithium disilicate glass-ceramics [1, 10]. This system was used to carry out extensive investigations on the stoichiometric relationships of the main components. Furthermore, new products were developed on the basis of this system [11–13]. Significant improvements of the properties of this type of glass ceramics were made by Beall [14] and Echeveria [15]. The glass-ceramic system was modified to produce a nonstoichiometric multicomponent system.

The development of biomaterials for dental restoration is also based on multicomponent systems. An important research result was the development of IPS e.max® in the preferred composition range of 64–73 wt % SiO_2 , 13–17 Li_2O , 2–5 Al_2O_3 , 0.5–5 K_2O , and 2–5 nucleating agent (preferably P_2O_5) [1, 2]. The most important scientific finding in the process was that, in this multicomponent system, the nucleation center was not in the form of a heterogeneous substrate or a metal colloid. Instead, the amorphous phase boundary between an amorphous phosphate phase and the glass matrix formed the starting point for the formation of the primary phase [1].

The microstructure of the IPS e.max® CAD and Press glass-ceramics is characterized by its interlocked nature and a high crystal content of more than 50 wt % (Figure 3b). The properties shown in Table 1 are achieved by the inorganic chemical composition and the particular microstructure of the glass-ceramics [1]. These properties allow the biomaterial to fulfill the requirements of restorative dental crowns (for anterior and posterior teeth, including molars) and dental bridges (in anterior teeth and up to the second premolar).

In order to facilitate machining of the IPS e.max® CAD glass ceramics according to the method described

for IPS Empress®, this material is cut in an intermediate “soft” state. For this purpose, the material is initially crystallized up to the lithium metasilicate (Li_2SiO_3) glass-ceramic stage. Lithium metasilicate is a chain silicate consisting of Q^2 (SiO_4 tetrahedron of two bridging and two non-bridging oxygen ions) structural units (Chapter 2.4). This type of glass-ceramics is easy to machine. After the material has been milled into the desired shape (e.g. dental crown), it is heat treated for a second time. In this process, the lithium disilicate acquires its final state of an interlocking crystal morphology.

4.3 Phosphate-Containing Glass-Ceramics

Another interesting material is made up of fluorapatite glass ceramics. Fluorapatite crystals $[\text{Ca}_5(\text{PO}_4)_3\text{F}]$ are orthophosphates that are built up out of isolated $[\text{PO}_4]^{3-}$ tetrahedra in typical Q^0 ($[\text{PO}_4]^{3-}$ tetrahedron of four non-bridging oxygen ions) structural units [1]. This crystal structure is shown in Figure 4. The nucleation process is controlled by a liquid–liquid phase separation. As a result, volume nucleation is initiated. The crystal growth process shows some very special features. The crystallization of the apatite phase, compared, for instance, with that of mica–apatite glass ceramics [1], proceeds in needlelike form. This particular growth process is typical of Ostwald ripening [1, 16, 17], which is known to yield a crystal morphology favorable to translucency. This type of biomaterial with its CTE of $9.5 \times 10^{-6} \text{ K}^{-1}$ and low sintering temperature of 750°C , therefore, can be used to veneer lithium disilicate glass-ceramics (Figure 1a) as well as ZrO_2 frameworks in restorative dentistry.

Besides, needlelike fluorapatite crystals can be simultaneously precipitated with leucite crystals in one glass-ceramic. This nucleation/crystallization process in which

Figure 4 Crystal structure of fluorapatite. Reproduced from [1] with permission from Wiley.

two crystal phases are grown (according to two different mechanisms) is known as *twofold nucleation and twofold crystallization*. These mechanisms have been successfully used to develop IPS d.SIGN® (Ivoclar Vivadent AG), for example, which serves to cover up metal frameworks (e.g. of multiunit dental bridges).

In 2015, Ivoclar Vivadent AG, Liechtenstein, introduced a newly developed glass-ceramics called IPS Style® Ceram. This product contains silicate-type oxyapatite crystals in addition to needlelike fluorapatite crystals. In contrast to calcium fluorapatite, the abovementioned orthophosphate, this phase is formed as a silicate crystal (nevertheless, with similar structural units as those of the phosphate phase, [18]) according to the mechanism of surface nucleation and surface crystallization.

5 Perspectives

The development of state-of-the-art materials for restorative dental applications will continue to focus on combining optimally different properties. Consequently, the processes of controlled crystallization must be further improved and optimized. For this purpose, the mechanisms of twofold nucleation and crystallization also need to be finely tuned [8].

Furthermore, ongoing advances in the field of digital dentistry will present new challenges in the development of new materials, particularly in terms of the enhancement of the optical properties of dental materials and

the refinement of processing techniques. As shown in [2], glass-ceramics fulfill the patient needs with high aesthetics and different properties, such as mechanical, thermal, and chemical, to allow the use of the material as dental restoratives as dental crowns, veneers, inlays, and bridges.

Relaxation Processes in Molecular Liquids

Thomas Blochowicz¹, Ernst A. Rössler², and Michael Vogel¹¹ Institut für Festkörperphysik, Technische Universität Darmstadt, Darmstadt, Germany² Experimentalphysik VII, Universität Bayreuth, Bayreuth, Germany

1 Introduction

The formation of glasses is ubiquitous in nature and technology, yet a full microscopic understanding of the phenomenon is still lacking. When a liquid is cooled without crystallization below the melting point T_m , its viscosity increases strongly, but continuously by about 15 orders of magnitude until it reaches values of an amorphous solid at the glass transition temperature T_g . This viscosity increase is associated with a tremendous slowdown of the structural (α -) relaxation on a molecular level, which ceases on typical experimental timescales at T_g , so the configuration is arrested and the system falls out of thermal equilibrium (Chapter 3.7).

As exemplified by oxide melts, *associated* liquids have complex structures that keep constantly rearranging and, therefore, lack long-lived structural entities. Differences in bond strengths do exist and lead, for instance, to distinguish network-forming and network-modifying ions whose respective dynamics progressively decouple upon cooling. The dynamics of the liquid as a whole is controlled by that of the network formers, however, with the consequence that the glass transition takes place when the mobility of these ions becomes successively slower.

Like polymers (Chapters 8.7 and 8.8), *molecular* liquids present a different picture. As indicated by their name, they possess well-defined structural entities as a result of large differences between intra- and intermolecular bonding. Of particular importance then are the rotational degrees of freedom that often can be easily accessed experimentally. The relevance of rotational dynamics is

most simply illustrated by *plastic* or *glassy* crystals in which molecules rotate within crystalline networks at high enough temperatures and freeze in upon cooling in random orientations with the phenomenology of the glass transition.

Such rotations also take place despite the abovementioned structural differences in molecular and network glass formers alike, but, as opposed to plastic crystals, within disordered and kinetically rearranging frameworks. In molecular liquids, molecular reorientations like viscosity display strong deviations from Arrhenius laws for the temperature dependence of α -relaxation. It remains a great challenge to explain this feature, which is not accompanied by obvious changes in liquid structure. For this purpose, it is not sufficient to study the glass transition in a narrow sense, i.e. to focus on phenomena near T_g like aging, but it is necessary to explore what is nowadays more generally called the *glassy dynamics* in a wide temperature range from its onset above T_m down to T_g [1, 2].

A first topic addressed in this chapter thus is how comprehensive characterization of the molecular slowdown requires to cover a broad dynamic range. Accordingly, numerous studies have exploited techniques like dielectric spectroscopy (DS) [3] nuclear magnetic resonance (NMR) [4], depolarized light scattering (DLS) [5], and optical Kerr effect (OKE) [6], because they provide access to rotational motions related to the glassy dynamics whereas single-particle as well as collective displacements can be accessed by neutron scattering [7]. Besides, broadband mechanical relaxation experiments have recently become feasible [8]. These methods work in the time or the frequency domains to probe either *correlation functions* (Chapter 2.2) or *dynamic susceptibilities*, which characterize the amplitudes of spontaneous fluctuations around the average value of the respective observables.

Reviewers: R. Böhmer, Fakultät Physik, Technische Universität Dortmund, Dortmund, Germany

F. Fujara, Institut für Festkörperphysik, Technische Universität Darmstadt, Darmstadt, Germany

For direct comparisons, it is thus beneficial to transform the respective data to a common representation.

The second point to be dealt with here is the temperature dependence of relaxation processes, i.e. the correlation functions or dynamic susceptibilities change upon cooling. For simple liquids well above T_m , the correlation functions decay in one step with temperature dependences that obey Arrhenius laws. Upon cooling, the glassy dynamics emerges and leads instead to two-step decays, which are found for inorganic glass-forming liquids like silicate melts as well [9]. They can be attributed to a temporary caging of structural entities by their neighbors in dense liquids. Whereas the first decay results from the *rattling* of these entities within the cages, the second reflects their escape from them and, thus, the α -relaxation. A characteristic feature of α -relaxation is that it is non-exponential or, equivalently, that it has a non-Debye nature because it cannot be described by a Lorentzian susceptibility. At least in a first approximation, the temperature dependence of the time constant, $\tau_\alpha(T)$, is often described with the empirical Vogel–Fulcher–Tammann (VFT) equation (Chapter 4.1). Other representations have proven useful, whereas much effort is also currently devoted to describe the pressure dependence of τ_α .

In a third part of this chapter, attention will be paid to the theories that have been proposed to rationalize the glassy slowdown, referring to available reviews for more detailed accounts [10]. The mode-coupling theory is a first-principles approach that provides detailed predictions for the shape of susceptibilities [11]. It captures many aspects of the onset of the glassy slowdown as demonstrated by experimental and simulation studies made in the last decades. In its original form, it predicts a divergence of τ_α at a critical temperature T_c , which turns out to be substantially higher than T_g . This problem has been addressed by a generalized mode-coupling theory aiming at reproducing the non-Arrhenian slowdown in the deeply supercooled regime. Other more phenomenological theories of the glass transition assume that the increasing temperature dependence of the α -relaxation results from growing length scales related to dynamical or structural properties of the liquid. The long-standing history of this concept dates back to Adam and Gibbs (Chapter 4.1) who proposed that cooperatively rearranging regions grow upon cooling. Various kinds of spatial heterogeneity form also the cornerstones of current theories such as the frustration-limited domain approach, the dynamic-facilitation concept, or the random-first-order transition theory [10]. Furthermore, elastic models of glass-forming liquids have been proposed. For example, the elastically cooperative activated barrier hopping theory [12] presumes that the α -relaxation involves coupled local

hopping and collective distortions of the local environment, resulting in two related but distinct energy barriers. As a matter of fact, the quest for a characteristic length scale is a major topic in experimental and computational approaches.

In the fourth part of this chapter, the focus will be put on binary glass-forming liquids, which are of great importance in various fields. Prominent examples range from polymer blends and mixtures of water with small molecules, where the molecular species often show comparable mobility, to polymer–plasticizer and protein–solvent systems with a high dynamical asymmetry. In view of the omnipresence of such mixtures, it is natural to proceed from neat to binary systems. In doing so, the established relaxation phenomenology of the neat counterparts is very useful for an interpretation of the even richer dynamical scenarios of binary glass formers, where the more mobile component can, for instance, undergo a glass transition in a disordered frozen matrix formed by the less mobile component. Vice versa, mixing often allows one to separate diverse relaxation features of neat systems, paving the way for more detailed studies.

The penultimate feature that will be discussed is the secondary (β -) relaxation that emerges when T_g is approached and eventually governs the overall relaxation in the glassy state. A prominent example is the Johari–Goldstein (JG) β -relaxation, which often splits off from the α -relaxation in the highly viscous regime to manifest itself even below T_g . Other relaxation phenomena in the glass state ($T < T_g$), however, in particular at cryogenic temperatures, are beyond the scope of this review. Finally, the particular case of glassy crystals will be described. Here the translational degrees of freedom exhibit crystalline order, whereas solely the rotational degrees of freedom show a glass transition, which makes it possible to consider them as model systems in studies of the glassy dynamics.

VFT	Vogel–Fulcher–Tammann

2 From the Boiling Point Down to the Glass Transition

2.1 Evolution of the Dynamic Susceptibility

In the frequency range 10^{-2} – 10^9 Hz, DS was and remains the most convenient method to characterize the dynamics of viscous liquids close to T_g [3]. Thanks to recent technical progress in the GHz–THz regimes, it has even become possible to cover the full spectral range of the dynamics of molecular liquids as illustrated by spectra recorded for glycerol [$C_3H_8O_3$] at different temperatures (Figure 1a) [3, 13]. Manifesting itself as a rather narrow peak, the primary or α -relaxation shifts to lower frequencies upon cooling, whereas a susceptibility minimum develops between the α -peak and the microscopic dynamics at highest frequencies, which includes the boson peak (Chapter 3.4, Section 6). This gap is filled by secondary relaxation processes that emerge as a fully developed β -peak or as an *excess wing* described by a $\omega^{-\gamma}$ power law (like in glycerol) [14]. Both types of relaxation survive below T_g . Because the α -peak itself cannot be described in terms of the single dielectric relaxation time of the Debye model, the Cole–Davidson function is often used to account for asymmetric peak broadening, explicitly, in terms of the complex susceptibility:

$$\chi_{\alpha}^*(\omega) = \frac{\Delta\chi_{\alpha}}{[1 + i\omega\tau_{CD}]^{\beta_{CD}}}. \quad (1)$$

Likewise, the Kohlrausch function is commonly employed to consider the non-exponential time dependence of the α -relaxation:

$$C(t) = \Delta\chi_{\alpha} e^{-(t/\tau_K)^{\beta_K}}. \quad (2)$$

Here, $\Delta\chi_{\alpha}$ denotes the relaxation strength, τ_i the characteristic time constant, and β_i the corresponding stretching parameter.

Beginning with the pioneering work of Cummins and coworkers [5], broadband DLS in the GHz–THz range with a double monochromator and tandem Fabry–Pérot interferometry has become another useful tool even for inorganic glasses [15]. The information obtained complement the DS dynamic susceptibility data, in particular at high temperatures, although it should be kept in mind that DS probes a rank-one rotational correlation function $C^{(1)}(t)$, whereas DLS (and NMR) probes a rank-two function $C^{(2)}(t)$, so systematic differences may occur. For ethylbenzene [C_8H_{10}], the spectral features observed by DLS (Figure 1b) are nonetheless similar to those derived from DS. Close to boiling point (T_b), the susceptibility minimum disappears, and the α -relaxation merges with the microscopic peak to become essentially a single maximum.

After transformation into the time domain, DLS data can be complemented by results from photon correlation spectroscopy (PCS), which probes molecular reorientation at longer timescales as exemplified by measurements made on m-tricresyl phosphate [$C_{21}H_{21}O_4P$] (Figure 2) [16]. The resulting evolution of the correlation function monitored over sixteen decades is best suited to summarize the general properties of glassy dynamics. These are (i) the two-step correlation function emerging upon cooling of a liquid from T_b ; (ii) its long-time decay showing relaxation stretching; (iii) the degree of stretching being virtually constant with decreasing temperatures down to T_g , so time– (or frequency–) temperature superposition (FTS) can be considered to apply; and (iv) the non-Arrhenian temperature dependence of the time constant $\tau_{\alpha}(T)$ (see below).

The first step in the correlation function reflects all kinds of fast dynamics, including the aforementioned cage rattling. Once glassy dynamics is established, no further change of the basic shape of the correlation function thus appears to be observable upon cooling. Such glassy dynamics is established well above T_m , which implies that simple liquid dynamics with a mono-modal correlation function and Arrhenius temperature dependence are if at all only found near T_b . In other words, glassy dynamics in the sense defined here is not restricted to the super-cooled regime, but is characteristic of dense liquids. In this respect, it is worth emphasizing that mode-coupling theory [11] essentially reproduces the onset of these relaxation features [7, 16].

The approximate validity of FTS for the α -process and excess wing of the susceptibility of glycerol is illustrated (Figure 3a) by the single master curve $\chi''(\omega\tau_\alpha)$ derived from DLS and DS broadband data and results from ^1H NMR relaxometry [16]. Although the excess wing is difficult to identify in the time domain because of its small relaxation strength, it is well recognized in the frequency domain. In the high-frequency regime of the excess wing, the DLS and DS susceptibilities are related by $\chi''_{(2)}(\omega) \cong 3\chi''_{(1)}(\omega)$. This difference can be rationalized in terms of small-angle reorientation, implying that the excess wing represents a spatially highly hindered motion and probably is a generic feature of molecular liquids [16].

Molecular glass formers have also been investigated by OKE experiments [6], which probe the same fluctuations as DLS through the changes in the refractive index of a material induced by an applied electrical field. The experiment monitors the pulse-response function $F_{\text{OKE}}(t) \propto -(\text{d}C^{(2)}(t)/\text{d}t)$ in a rather wide time window. This representation of the data is particularly useful for an identification of different power law regimes contained in the main correlation loss. Regarding the α -relaxation peak and the excess wing, their short-time power law exponents β and γ reappear as $F_{\text{OKE}}(t) \propto t^{-(1-\beta)}$ and

$\propto t^{-(1-\gamma)}$, respectively. For liquids as diverse as benzophenone [$\text{C}_{13}\text{H}_{10}\text{O}_1$], glycerol, and m-tricresyl phosphate [$\text{C}_{21}\text{H}_{21}\text{O}_4\text{P}$], two power laws are seen (Figure 3b) at shorter and longer times, the latter being the high-frequency part of the α -process. Although the first has been termed the intermediate power law [6], it appears to be nothing else but the excess wing as demonstrated in Figure 3b where the DS and PCS data included also show a second power law at short times [16].

The effect of pressure on the susceptibility spectra has also been investigated thoroughly [17]. It turns out that the susceptibility spectra of many glass formers (except hydrogen-bonded systems) are similar in the region of the α -process if the different P and T of the measurement are selected so as to ensure the same values of τ_α . This fact is not a surprising if one assumes that FTS is a generic feature of the glass transition, i.e. that relaxation stretching is not altered by changes in T or P . From 50 °C and 0.1 MPa to 90 °C and 215 MPa (Figure 4) [17], this *isochronal superposition* of α -relaxation is nicely illustrated by the dielectric spectra of phenolphthalein dimethylether [$\text{C}_{22}\text{H}_{18}\text{O}_4$].

Altogether, various experimental techniques yield a consistent picture for the evolution of the dynamic susceptibility associated with the rotational dynamics of molecular liquids approaching T_g . These findings are complemented by results from neutron scattering, which probes equally well the corresponding displacement dynamics though in a significantly narrower dynamic range [7]. For some glass formers, a distinct secondary relaxation is not observed. Hence, changes in the spectral shape are dominated by the emergence of the excess wing on the high-frequency flank of the α -relaxation peak.

2.2 Time Constants

A major challenge posed by the glass transition phenomenon is to arrive at a consistent description of $\tau_\alpha(T)$ as obtained from different experimental techniques.

Figure 3 Relaxation in molecular liquids in different representations. (a) Dynamic susceptibility of glycerol as a function of reduced frequency determined by DS, field-cycling ^1H NMR, DLS (DM, double monochromator; TFPI, tandem Fabry–Pérot interferometry), and PCS; arrow indicates a factor 3 between the amplitudes of the excess wing. (b) Pulse-response representation of relaxation as a function of reduced time: two power laws seen for benzophenone (BZP) in optical Kerr effect (OKE) data [6], for glycerol in dielectric data, and for m-tricresyl phosphate (m-TCP) in PCS data; dashed lines indicate intermediate power law/excess wing; dotted lines reflect the α -process. Source: Adapted with permission from Ref. [16]. Copyright 2013 AIP Publishing.

Regarding molecular reorientation, however, various methods do yield comparable time constants. To describe their temperature dependence, the VFT formula is often applied in spite of high-temperature shortcomings and of doubts raised on the implied divergence of the correlation time at low temperatures. To test its validity, the VFT relation can be explicitly recast in terms of the fragility index m , T_g , and τ_∞ [18]:

Figure 4 Relaxation at different temperatures and pressures: isochronal superposition. The spectral shape of the dielectric relaxation of phenolphthalein dimethylether (PDE) agrees for different pressure–temperature combinations yielding the same structural relaxation time τ_α . Source: Courtesy M. Paluch.

Figure 5 Reorientational correlation times of molecular liquids (solid symbols) and polymers (open symbols): experimental data and VFT fits (solid lines) made as a function of the reduced variable of Eq. (1), m being the fragility index. Scaled viscosity of the NBS 711 silicate melt included for comparison (cross).

$$\lg \frac{\tau_\alpha}{\tau_\infty} = \frac{K_0^2}{m(T/T_g - 1) + K_0}. \quad (3)$$

Here, $K_0 = \lg(\tau_\alpha(T_g)/\tau_\infty)$, whereas the parameter $m = \left. \frac{\partial \lg \tau_\alpha}{\partial (T_g/T)} \right|_{T=T_g}$ specifies the *steepness* at T_g in an

Angell plot $\lg \tau_\alpha$ vs. T_g/T . Comparisons made on the basis of Eq. (1) indicate that the VFT relation works well up to highest temperature for polymers but clearly fails for molecular liquids as well as for the NBS 711 standard silicate melt (Figure 5).

Figure 6 Reorientational correlation times of molecular liquids. (a) Arrhenius plots of data for molecular liquids with glass transition temperatures ranging from 115 to 343 K. Dashed lines: high-temperature Arrhenius fits. Solid curves: interpolations made with Eq. (4). Source: Reprinted with permission from Ref. [16]. Copyright 2013 AIP Publishing.

Many other approaches have been proposed to interpolate $\tau_\alpha(T)$, but none is widely accepted because molecular glass formers have been little studied above T_m , the available data being usually restricted to $\tau_\alpha(T) > 10^{-9}$ seconds. Yet, as already noted, susceptibility spectra and, thus, correlation times down to 10^{-12} seconds are now easily accessible by DLS. Such $\tau_\alpha(T)$ data obtained from DS and DLS/PCS measurements are thus especially valuable as they may cover the entire temperature range between T_g and T_b . Clearly, an Arrhenius law with the activation energy E_∞ is obeyed at higher

temperatures before the effective activation energy $E(T)$ strongly increases when T_g is approached (Figure 6). Although the quantity E_∞ must not be associated with some single-particle barrier in a liquid, one can take the high-temperature Arrhenius law as an empirical limit and decompose $E(T)$ into two parts, namely, $E_{\text{coop}}(T)$ and E_∞ [16]:

$$\tau_\alpha(T) = \tau_\infty \exp \left(\frac{E_\infty + E_{\text{coop}}(T)}{T} \right). \quad (4)$$

With the assumption that $E_{\text{coop}}(T)$ is an exponential function of temperature, one can then plot $E_{\text{coop}}(T)/E_\infty$ against T/E_∞ in a generalized Angell representation [16]. This analysis thus assumes that the energy scale of the glass transition is not set by T_g , but by the experimentally accessible high-temperature quantity E_∞ . Once the influence of E_∞ and $E_{\text{coop}}(T)$ is disentangled in this way, a new measure of fragility can be introduced. It is the steepness in $E_{\text{coop}}(T)/E_\infty$ vs. T/E_∞ plots, which clearly distinguishes a highly fragile liquid such as o-terphenyl [$\text{C}_{18}\text{H}_{14}$] from the much less fragile propylene glycol [$\text{C}_3\text{H}_8\text{O}_2$]. Whether the increase of $E_{\text{coop}}(T)$ or the apparent activation energy of $\tau_\alpha(T)$ is connected to some growing correlation length is a matter of recent experiments as well as theoretical considerations. Here two further points only will be noted. The first is that the phenomenological approach of Eq. (4) bears some similarity with the description introduced by the elastically cooperative activated barrier hopping theory [12]. The second is that diffusion data have to be excluded from the present discussion as they show a *decoupling phenomenon*, i.e. that the Stokes–Einstein relation (Chapter 4.3) is violated [19].

Figure 7 Relaxation times at different temperatures and pressures: temperature–density scaling of time constants τ_α as function of the parameter $X = \rho^\gamma/T$ for different molecular glass formers [17]. Source: Courtesy M. Paluch.

Attempts have been made to correlate the usual fragility index m with some other property of the liquid, for instance, the stretching parameter β , the Poisson ratio, or the so-called non-ergodicity parameter (relative amplitude of α -process) [2]. Yet, no correlation between m and β has been reported in recent surveys. Except for hydrogen-bonded liquids, the fragility actually varies only weakly among molecular liquids.

For deeper analyses, high-pressure measurements are in fact needed because lowering the temperature of a liquid at constant pressure causes at the same time a decrease in thermal energy and an increase of density, the contributions of which cannot be disentangled. Extensive measurements have thus been made at elevated pressure [17] to determine correlation times as a function of temperature and density, $\tau_\alpha(T, p)$, and to express them in terms of some scaling function $J(X)$. For $X = \rho^\gamma/T$ (Figure 7), an exponent $\gamma = 4$ can, for example, be derived for the Lennard-Jones potential (Chapter 2.8) when assuming an r^{-12} repulsive term and disregarding the attractive part. But the value of γ varies for different systems since this simple interaction potential is much too approximate for molecular liquids.

2.3 The Search for a Characteristic Length Scale

The dramatic increase of timescales in supercooled liquids has been assigned to growing length scales of heterogeneous and to collective structural rearrangements in many studies of the glass transition [1, 10].

Despite much research, however, the nature of the entities that determine this relaxation slowdown remains controversial.

It is well established that dynamical heterogeneities are key features of dense liquids [10, 19]. Computer simulations, in particular molecular dynamics (MD) simulations, have been a valuable tool to show that fast and slow particles are not randomly distributed in the weakly supercooled regime, but spatially correlated (Figure 8). The space–time characteristics of dynamical fluctuations have been evaluated in different ways. To quantify the amplitude of spontaneous fluctuations around the average dynamics, a four-point, time-dependent density correlation function and its volume integral, the generalized dynamic susceptibility $\chi_4(t)$, are commonly used [10]. The spatial correlations between the mobility of particles are of a transient nature, but they increase upon cooling, thus pointing to growing dynamic length scales.

Likewise, particles with high or low mobility form clusters, the sizes of which increase with decreasing temperatures. Such spatially heterogeneous dynamics has been reported not only for atomic and molecular systems [20, 21] but also for a model of silica melt [9]. As an example, MD simulations of a monoatomic liquid reveal an increasing spatial heterogeneity upon cooling in the form of a distinct maximum in the time-dependent mean size of clusters consisting of highly mobile particles (Figure 9a). In more detail, the highly mobile particles show a cooperative string-like motion [21] through which they follow one another along a one-dimensional

Figure 8 Molecular dynamics simulations of spatially heterogeneous dynamics in supercooled liquids. Figure 9 Molecular dynamics simulations of highly mobile particles in a monoatomic supercooled liquid at various temperatures [20]. (a) Time-dependent weight-averaged cluster size $S_W(t)$. (b) Corresponding string length $L_W(t)$. Inset: example of string-like motion, light and dark spheres visualizing the positions of the same particles at the beginning and at the end of a time interval with the string motion, respectively.

pathway. The time-dependent mean length of these strings grows upon cooling, implying that this cooperative motion becomes an important relaxation channel at low temperatures. The cluster size and the string length reach maximum values when the particles begin to escape from their local cages, so the clusters or strings may be involved in the elementary step of the α -relaxation. Accordingly, these entities have been considered as supporting the dynamic-facilitation concept [2, 10]. Whereas clusters are also considered to be key elements of the α -relaxation of silica melt, such strings are not relevant to this network-forming material.

Owing to computer limitations, these simulations are still restricted to high temperatures, say, $\tau_\alpha < 1 \mu\text{s}$. Challenging experimental work is thus required to follow the dynamic length scales down to T_g . In an NMR approach, 4-D cross-polarization experiments have yielded evidence for a spatially heterogeneous dynamics near T_g at a length scale of about 3 nm [10]. Likewise, a switch between fast and slow dynamical states has been observed by atomic force microscopy in regions that have a size of a few nanometers [10]. The temperature dependence of the dynamic length scale has also been recently addressed. Even though the four-point dynamic susceptibility still awaits direct measurement for viscous liquids, the experimentally accessible responses of correlation functions to temperature or pressure changes yield lower bounds of $\chi_4(t)$.

A growing dynamic length scale is indeed related to the glassy slow down as the maximum of the estimated $\chi_4(t)$ can be regarded as a measure of the number of molecules, N_{corr} , that are dynamically correlated at the timescale of the α -process. In the various liquids considered, a fast increase of N_{corr} at higher temperatures is followed by a slower growth at lower temperatures [22]: when the α -process slows down by roughly six orders of magnitude, N_{corr} increases by only a factor of 2 (Figure 10a).

Recently, it has been argued that the *a.c.* nonlinear dielectric response $\chi_3(\omega)$ opens another way for a determination of N_{corr} [23] because its maximum value would be a direct estimate of N_{corr} . Although the argument has been disputed, there is a simple relation between $N_{\text{corr}}(T)$ and the effective activation energy of the α -process, $E(T)$ (Figure 10b). This finding has been taken as evidence that the nontrivial temperature dependence of the glassy dynamics is caused by an increasing energy barrier arising from a growing number of cooperatively moving particles.

To determine length scales, another fruitful approach consists in studying liquids confined in very narrow spaces since deviations from bulk properties result as soon as a characteristic length scale is reached. But unambiguous analyses of such finite-size effects are often hampered by liquid–matrix interactions, i.e. interface effects, which are of course much easier to avoid in computational than in experimental studies especially if the matrix is composed of the same type of particles as the confined liquid (Figure 11a). Through calculations of position resolved correlation times (Figure 11b), it then appears that the dynamics of water strongly depends on the nature of the confinement wall. It is in particular about 100 times slower in the immediate vicinity of pinned water molecules than at larger distances even though peculiar attractive liquid–matrix interactions are absent [25].

A *dynamic length* ξ_d can in addition be obtained from an analysis of the distance up to which the dynamics of unpinned molecules is perturbed by their pinned counterparts. For water, one finds in this way that ξ_d increases by roughly a factor of 2 when the temperature decreases from 300 to 200 K [25]. The *static length* ξ_s also derived from neutral confinement conditions [25, 26] is a characteristic length up to which the positions of pinned and unpinned particles are substantially correlated. Comparing the

Figure 10 Number of dynamically correlated molecules in various glass-forming liquids as a function of temperature. temperature dependences of the length scales ξ_d and ξ_s for a binary mixture of quasi-hard spheres [26], one finds that ξ_d exhibits a non-monotonic temperature evolution with a maximum near the critical temperature T_c of mode-coupling theory, whereas ξ_s steadily grows upon cooling. These contrasting trends are consistent with the random-first-order theory of the glass transition and suggest a crossover from *flow* to *hopping* motion near T_c [10].

3 Binary Glass-Forming Liquids

One-component molecular glass formers provide a valuable basis for the interpretation of the richer dynamical scenarios observed when different components are blended. Interest in multicomponent systems is to a great part triggered by their omnipresence in both everyday life and technological applications for which composition is often used to tailor material properties [27]. For such systems, however, a fundamental understanding is hampered by an overwhelming complexity, so approaches often focus on binary mixtures as simple model systems.

The outstanding dynamical properties of two-component systems are pronounced dynamical heterogeneities observed as broadened or even bimodal distributions of relaxation times that may be associated with violations of FTS [28, 29]. These heterogeneities have been explained in terms of local concentration variations that are either thermally driven or induced by the chain connectivity around one polymer segment.

Special attention has been paid to dynamically very asymmetric mixtures where additional effects come into play. Such mixtures are characterized by a high- T_g contrast between the individual components, which remain entirely miscible in spite of their strong dynamical decoupling. When undergoing isotropic reorientation far below the glass transition of the larger molecule [30], the smaller species may in fact experience the confinement exerted by a rigid matrix akin to that of supercooled liquids within nanometric pores [31].

Macroscopic miscibility does not necessarily imply a unique glass transition. Two transitions have been reported instead in miscible polymer blends and polymer-plasticizer systems as well as in mixtures of small organic molecules. A good example is that of 2-methyltetrahydrofuran ($C_5H_8O_2$) mixed with polystyrene (Chapter 8.8) of different molecular masses

Figure 12 Double glass transition in binary mixtures. (a) 2-Methyltetrahydrofuran in polystyrene (PS) as observed by dielectric spectroscopy (DS) (crosses) and differential scanning calorimetry (other data) for the molar masses indicated (g/mol, TS: trimer). (b) Tripropyl phosphate (TPP) in polystyrene (2 kg/mol): T_g as a function of concentration (mass percent) determined by DSC, DS, and NMR. *Source:* Reprinted with permission from Ref. [30]. Copyright 2014 AIP Publishing.

[32]. While the higher T_g strongly varies with composition and turns out to represent the α -relaxation of the matrix, the lower T_g changes much less as a result of the decoupling of the intrinsic α -relaxation of the small molecules (Figure 12a). Similar features are observed for tripropyl phosphate [$C_9H_{21}O_4P$] (Figure 12b), with the difference that the lower T_g displays a maximum at an intermediate concentration [30].

In accordance with the observation of two T_g , two different relaxation processes are observed in the dielectric spectra of binary mixtures (Figure 13). For the considered examples, DS essentially probes the relaxation of the small molecules due to strongly different dipole moments of the components. As is common in one-component glass formers, FTS holds reasonably well for the slower α_1 -relaxation, which is related to small molecules coupling to the matrix dynamics in spite of some peak broadening compared with the neat liquid (Figure 13b). By contrast, for the decoupled small molecules, pronounced FTS violations are observed (Figure 13c). In particular, the broadening observed on the low-frequency side of the peak caused by the presence of rigid walls is similar to that observed for supercooled liquids confined in nanoporous media [31].

At first glance, relaxation faster than the slowest α -process might be considered as secondary as it often shows Arrhenius temperature dependence. However, it turns out that the α_2 -process is associated with the second T_g in calorimetry (Figure 12). As indicated by NMR spectra, it involves isotropic reorientation of the smaller component in the frozen matrix [30]. Consistently, further

component-selective experiments show that the small molecules are associated with both α -relaxations (Figure 14).

As an example, Figure 14a shows the motion of 2-methyltetrahydrofuran, which can be selectively probed in a mixture with polystyrene 60k, by selective deuteration with QENS and due to the permanent dipole moment by DS. It then appears that the temperature dependence of the fast relaxation of the small molecules, which are embedded in an largely immobilized matrix of large molecules, changes from non-Arrhenian to Arrhenian below T_{g1} (Figure 14b), a so-called fragile-to-strong crossover, which is also observed in nanopore confinement experiments [31]. In addition, the small molecules take part in the slower α_1 -relaxation only below a certain temperature T_c . Above it, they relax without any coupling with the dynamics of the matrix. Below T_c , a fraction of the small molecules can only relax together with the α -process of the matrix [30, 32]. Interestingly, such a dynamic decoupling of large and small particles is predicted by MCT if the components differ sufficiently in size [33], in which cases the calculated correlation functions resemble that of Figure 14a. For quenched-annealed systems, this theory [34] in particular predicts higher-order singularities in the vicinity of which the correlation functions of the smaller molecules become particularly broad, e.g. quasi-logarithmic, consistent with the results of both simulations and experiments [35].

In conclusion, decoupling between the component dynamics in binary systems results in dynamical heterogeneities such that the α_1 -relaxation of large molecules

remains rather similar to that of neat glass formers, whereas the α_2 -process of small molecules is characterized by a strong broadening of the corresponding distribution $G_{\alpha 2}(\ln \tau_{\alpha 2})$, which may lead to the aforementioned quasi-logarithmic decays at low concentration. Even below T_{g1} , dynamic exchange occurs within $G_{\alpha 2}(\ln \tau_{\alpha 2})$, so fast molecules become slow and vice versa at a certain timescale. As illustrated by tripropyl phosphate (Figure 15), this exchange can be monitored by 2-D NMR spectroscopy whereby a cross-like pattern points to an exchange of correlation times between slow and fast molecules below 280 K, *slow* and *fast* referring here to

timescales longer and shorter than 10^{-5} seconds, respectively [30].

4 Secondary Relaxations

In addition to the α -processes, molecular systems show further relaxation features at higher frequencies such as the aforementioned excess wings, which emerge when approaching T_g [13, 17]. As an example (Figure 16a), DS measurements for sorbitol [$\text{C}_6\text{H}_{14}\text{O}_6$] show a pronounced β -relaxation peak that persists below T_g

Figure 16 Double relaxation of sorbitol: α - and β -process. (a) Evidence from dielectric spectra. (b) High-temperature merging of the two relaxation peaks shown by the convergence of their associated time constants. Source: Reprinted with permission from Ref. [36]. Copyright 2007 IOP Publishing.

[36]. In many cases, the β - and α -processes merge at high temperatures, leaving the single α -relaxation displayed by sorbitol (Figure 16b). At $T < T_g$, its mean logarithmic correlation time τ_β follows an Arrhenius law with an activation energy $\langle E_\beta \rangle = 10\text{--}30 RT_g$, whereas its spectrum broadens with decreasing temperatures.

Secondary relaxation processes are observed in ionic and metallic glasses and in glasses of rigid molecules like toluene [13], indicating that they do not rely on intramolecular degrees of freedom. In some cases, both a β -relaxation and an excess wing are observed. Further relaxation features related to the low-temperature anomalies of glasses dominate at cryogenic temperatures but will not be discussed here.

Attempts have been made at classifying secondary processes [17]. For instance, it has been stated that the excess wing is a hidden β -process, which may separate from the α -peak under pressure or physical aging. In another group, JG β -relaxation exhibits a high sensitivity to pressure and is regarded as a genuine feature related to α -relaxation although its origin first remains unclear. Other secondary relaxations that do not fit in this scheme were interpreted to be of a *local* nature. However, molecules can only move in a concerted way in an isostructural state ($T < T_g$), thus the β -relaxation is likely not of local origin. Exceptions are symmetry-controlled motions such as rotation of methyl groups. Early attempts postulated *islands of mobility* representing some defects in the glass structure [37]. Yet, as demonstrated by NMR [38] studies, essentially all molecules participate in the JG β -process whose dynamics can be described by spatially highly hindered reorientation. Recent findings for binary glasses, however, suggest that this statement might not generally hold true [39].

The major features of separate β -peaks at ambient pressure displayed by viscous liquids can be summarized most conveniently based on DS results. With decreasing temperatures, one can map the spectral broadening of the JG β -relaxation onto a temperature-independent distribution of activation energies $g(E)$ [13]. Regarding the relaxation strength, it is nearly constant below T_g , but it begins to increase strongly upon heating through T_g , reflecting the *softening* of the material above the glass transition. Actually NMR results indicate that the extent of spatial restrictions during the JG β -relaxation is reduced above T_g [38].

The JG β -process of several glass-forming liquids as well as of glassy crystals has been investigated by ^2H and ^{31}P NMR with two-pulse echo sequences [38, 39]. Owing to its high sensitivity to small-angle reorientations, this technique yields a clear picture of the nature of the β -process. For several systems including plastic crystals (Figure 17), the NMR spectra show very similar line-shape changes. The exception is glycerol, which does not display a well-resolved β -process (Figure 1a). Specifically, when increasing the delay between the pulses, a decrease of the spectral intensity around zero frequency is observed if the pulse delay is similar to the correlation time τ_β . One can reproduce well the spectra by taking recourse to a wobbling-on-a-cone model with a cone angle lower than 10° . Investigations of the β -process in mixed glasses have shown that the different components participate in the β -process independently of their shape and size [38]. For polymer-plasticizer systems, both the polymer chains and the plasticizer molecules participate in the β -relaxation, pointing to a cooperative nature of the β -process [39]. Finally, we note that the β -process is also probed by DLS, although its appearance in DLS may depend on details of the molecular structure (Figure 18) [16, 40].

Figure 17 Johari–Goldstein relaxation observed in ^2H NMR solid-echo spectra for different pulse delay t_p for cyanocyclohexane plastic crystal (CCH) and toluene (TOL), ethanol (ETH), and glycerol (GLY) glasses. Spatially highly hindered motion of essentially all molecules allows one to simulate (SIM) in the spectral changes with increasing t_p [38].

5 Plastic and Glassy Crystals

Calorimetric and dielectric studies were also among the first to show that certain crystals exhibit features well known in supercooled liquids [41]. Because dielectric spectra probe the reorientation of dipolar molecules, which may persist in the crystal, such molecular rotation becomes sufficiently slow to be arrested below some temperature, provided that a transition to a rotationally ordered phase does not occur. Indeed, the calorimetric signature of a glass transition is found, indicating, by analogy with supercooled liquids, that cooperative molecular reorientation becomes too slow to be observed at the timescale of the experiment. Moreover, the non-Arrhenius temperature dependence of the main (α -) relaxation is revealed and even β -processes are observed as shown by cyanocyclohexane (Figure 18a) [42]. Such crystals with cooperative rotational dynamics must be

distinguished from the so-called rotor phases like crystalline benzene where the molecular reorientation reflects a high symmetry of the molecule and cooperativity is not involved. Below T_g , the centers of the molecules form a three-dimensional lattice (often of cubic symmetry), but their orientations are arrested in a more or less random fashion, which is why the term *glassy crystal* has been coined.

Many plastic crystals have been studied [43]. A prominent example is ethanol, which forms a metastable plastic crystal upon sufficient supercooling (Figure 18b) [44]. In spite of somewhat different fragilities, this crystal and the liquid have the same $T_g = 98$ K. Most intriguingly, the dielectric spectra of both phases are almost indistinguishable (Figure 18b): a strong main (α -) process, a β -process with its Arrhenian time constant $\tau_\beta(T)$, and even traces of an excess wing are recognized. Most importantly, the NMR signature of the β -process

cannot be distinguished from that of a β -process in molecular liquids (Figure 17). Thus, spatially highly restricted reorientations are involved, too.

Somewhat different DS spectra (Figure 19) are found for o-carborane [$\text{C}_2\text{B}_{10}\text{H}_{12}$] [45]. In this case, the main relaxation strongly broadens upon cooling, so FTS does not apply and the spectra can be fully described by Cole–Davidson functions, i.e. no secondary relaxation emerges above T_g . For the plastic phase of cyanoadamantane [$\text{C}_{10}\text{H}_{15}\text{CN}$], 2-D ^2H NMR shows that the reorientation takes place via jumps of 90° determined by the cubic structure of the lattice; no free isotropic rotation occurs close to T_g (Figure 20) [46].

6 Perspectives

From high temperatures down to the glass transition, significant progress has recently been achieved in elucidating

the generic dynamics of molecular liquids at timescales ranging from picoseconds to seconds. This progress has been made possible by improved experimental techniques, which are increasingly able to cover the full frequency and temperature ranges with high precision. Yet, many aspects, although quite universally observed in many types of molecules, remain poorly understood. First of all, there is still no generally accepted theory of the glass transition. Aside from further ongoing developments of MCT, ideas related to the random-first-order transition theory have recently received a considerable attention as simulations and dedicated experiments have shed new light on the time-honored topic of growing length scales upon supercooling. At the same time, supercooled liquids are investigated in increasingly complex environments, such as multicomponent systems or nanoscale confinement, that are relevant to biology or technological applications. Because dynamic scenarios are even more complicated in such contexts, theoretical advances are badly needed to remedy the currently rather rudimentary state of understanding of these phenomena.

Acknowledgments

Financial support of the Deutsche Forschungsgemeinschaft (DFG) through the projects BL 923/1, BL1192/1, RO 907/10,11,15, and VO 905/8,9,10 is acknowledged. The authors thank P. Lunkenheimer (Augsburg), M. Paluch (Katowice), and M.D. Fayer (Stanford) for providing DS and OKE data, respectively. The careful proofreading by D. Bock (Bayreuth) is appreciated.

Physics of Polymer Glasses

Jean-Pierre Cohen-Addad

Laboratoire LiPhy, Université J. Fourier, Grenoble, Saint-Martin d'Hères, France

1 Introduction

Known since the early use of the milky latex of the rubber tree (*Hevea brasiliensis*), polymeric matter was first synthesized in 1870 as a substitute for ivory in the form of celluloid by reaction of nitrocellulose $[\text{C}_6\text{H}_7(\text{NO}_2)_3\text{O}_5]$ with camphor $[\text{C}_{10}\text{H}_{16}\text{O}]$. Usually, however, one rather assigns to 1909 the birth of the *plastics era* with the invention in the US of bakelite $[(\text{C}_6\text{H}_6\text{O}\cdot\text{CH}_2\text{O})_n]$ by the Belgian-born chemist Leo Baekeland because this new material formed through polycondensation of phenol $[\text{C}_6\text{H}_6\text{O}]$ with formaldehyde $[\text{CH}_2\text{O}]$ quickly found many applications thanks to its electrically insulating and heat-resistant properties. Since then, several hundreds of organic macromolecules have been synthesized, and the world production of plastics has reached 335×10^6 tons in 2016. From food containers, insulating foams and films to prostheses, and complex optical components, plastics have become so ubiquitous in daily life that, despite their strongly technical nature, terms such as polystyrene, polyethylene, polypropylene, polyurethane, and even polycarbonate are now household names (Chapter 8.8).

That these materials are basically glassy is highlighted by the name *Plexiglas* commercially given to methyl polymethacrylate when it was introduced on the market in 1933. This glassy character lies at the root of most uses of plastics as these materials can be shaped into any form, like oxide glasses, but more readily so in view of glass transitions occurring at temperatures always lower than

500 K. Because most plastics are primarily made up of the light elements C, H, O, and N, they have the important advantage of a low density of only $\sim 10^3 \text{ kg/m}^3$ combined with a definite resistance to breakage and a good chemical inertness. Finally, although they suffer from being combustible materials, their strength can be improved through partial crystallization or incorporation of mineral particles.

Plastics owe their fundamental importance to the nature of their macromolecular elements. All of them represent a sequence of a number as large as 10^4 of concatenated identical monomeric units that form a chain, whence the common prefix *poly* they share. Each macromolecule may be represented as a hairlike filament at a scale much smaller than $1 \mu\text{m}$. The main question dealt with in this chapter is how such a microscopic feature translates into the bulk plastic properties that make these amorphous organic materials so valuable.

For this purpose, attention will be first paid to the characteristic elasticity of a macromolecule in the liquid state, which results from the flexible concatenation of units subjected to a mechanism of rotational isomerization. We will then focus on the concept of fractional free volume as applied to the interpretation of the temperature dependence of viscoelastic response of polymeric liquids. This response is associated with a hierarchy of relaxation rates, which govern the segmental rearrangements of chains associated with the glass transition. Their signature will be discussed with respect to a variety of physical properties. Attention will also be paid to local chain rearrangements that give rise to secondary transitions below the glass transition region. Finally, the influence of partial crystallization and addition of mineral particles on polymer properties will be briefly discussed, and some applications of polymer science to films, fibers, foams, hollow fibers, and porous membranes will be described.

2 Polymeric Chains

2.1 Polymer Macromolecules

In preamble, some fundamental properties of the constituents of polymeric liquids must be described. As already stated, any polymeric material is made up of macromolecules formed from long sequences of concatenated identical monomer units linked to one another by covalent bonds, which define the skeleton of each molecule; for example, $-\text{CH}_2-\text{CH}(\text{C}_6\text{H}_5)-$ and $-\text{O}-\text{Si}(\text{CH}_3)_2-$ chemical groups are the monomer units of polystyrene and silicone chains, respectively. The synthesized macromolecules may comprise a number N of monomeric units as large as 10 000 so that the length of a fully extended chain skeleton may be of the order of $1\ \mu\text{m}$, whereas its diameter may be as small as half a nanometer. The very high ratio between the length of a polymer chain and its mean diameter is a feature analogous to that of a hair; it underlies all characteristic properties of polymeric matter.

2.2 Skeletal Bond Rotations

Chain skeletons are usually successions of carbon ($-\text{C}-\text{C}-$) or oxygen and silicon atoms ($-\text{Si}-\text{O}-$, in silicone); in most descriptions of the physical properties of macromolecules, bond lengths are considered as fixed and angles between any two successive bonds supposed to be constant. In molten polymers or in polymer solutions, each skeletal bond within a macromolecule can rotate about the axis defined by its preceding bond, so two angles per bond are required to specify the conformation of one chain in space. We will thus denote by θ the angle between two successive bonds and by ϕ the angle of rotation of one bond about its preceding one. Such bond rotations are a fundamental feature because they cause chains to be highly flexible and polymers to be highly elastic at a macroscopic scale. For polystyrene, a schematic representation of a succession of three ($-\text{C}-\text{C}-$) bonds, with phenyl groups and hydrogen atoms attached to the skeleton, is shown in Figure 1.

Owing to the very large number of its internal degrees of freedom, each macromolecule is considered as a physical system as a whole in the sense that usual thermodynamic functions (entropy, internal energy, free energy) can be applied to describe its properties within the framework of statistical physics. But it must be emphasized that the presence of side chemical groups bound to the chain skeleton, like methyl groups in silicones, for example, hinders internal rotations of monomeric units so that interactions between contiguous side groups give rise to an internal cooperative behavior along each macromolecule.

Figure 1 Schematic representation of the succession of three ($-\text{C}-\text{C}-$) skeletal bonds with phenyl groups and hydrogen atoms (H) attached to the chain.

2.3 Chain Stiffness

The interdependence of bond rotations determines chain stiffness as quantified by the *characteristic ratio* C_∞ , which is defined as the limit, for long chains, of the ratio of the mean square distance between the ends of a macromolecule $\langle R^2 \rangle$ and the sum of square lengths of skeletal bonds. If one assumes that each skeletal bond is defined from a vector $\mathbf{l}_j$, the end-to-end vector $\mathbf{R}$ is the sum over bond vectors:

$$\mathbf{R} = \sum_j^n \mathbf{l}_j, \quad (1)$$

where n is the total number of skeletal bonds in one chain. The mean square end-to-end distance then reads

$$\langle R^2 \rangle = \left\langle \sum_j^n \mathbf{l}_j^2 + \sum_j^n \sum_{j \neq k}^n \mathbf{l}_j \mathbf{l}_k \right\rangle. \quad (2)$$

In the case of equal bond lengths, the characteristic ratio is expressed as

$$C_\infty = 1 + \frac{1}{nl^2} \left\langle \sum_j^n \sum_{j \neq k}^n \mathbf{l}_j \mathbf{l}_k \right\rangle. \quad (3)$$

The second term on the right-hand side of Eq. (3) accounts for the effect of interrelated rotations of skeletal bonds in real chains. If hindrance to bond rotations is neglected, the characteristic ratio C_∞ is expressed as

$(1 + \cos(\pi - \theta))/(1 - \cos(\pi - \theta))$ whose value is thus 2 for tetrahedrally bonded chains ($\theta = 109^\circ 28'$). In real chains, the deviation from this value reflects the extension of correlations of bond vector orientations with respect to a given skeletal bond: the memory of correlations of bond orientations spreads over a chain segment length equal to lC_∞ on average. All studied chains exhibit a characteristic ratio higher than 4, the experimental values of C_∞ lying in the 4.0–10.0 range as shown by data summarized for real chains [1, 2].

The mean square end-to-end distance $\langle R^2 \rangle$ is conveniently measured from light scattering and/or viscosity experiments performed on ideal and dilute polymer solutions [3]. Ideal conditions are realized within short concentration and temperature ranges specific to a given polymer/solvent mixture; these conditions are obtained when the excluded volume effect resulting from interactions between pair of monomer units and solvent molecules cancels out. Correspondingly, the distribution of units in space obeys Gaussian statistics for long flexible chains. Light scattering experiments require that average chain sizes be comparable to the wavelength of light. Both types of experiments provide numerical values of $\langle R^2 \rangle$: the chain stiffness can be then quantified from the ratio $\langle R^2 \rangle m_u / M l^2$, where M is the chain molecular weight, whereas m_u is the mean molecular weight per skeletal bond.

2.4 Rotational Isomers

Potential energies of steric repulsion between atoms and chemical groups attached to neighboring units hinder the internal rotations of skeletal bonds; these energies strongly depend on the distances between all atoms along a given chain. The averaging of physical properties over all conformations possibly achieved by a chain then depends on the sum of these potential energies; consequently, skeletal bonds cannot be considered as statistically independent from one another within the framework of statistical physics. Every chain is in fact analogous to a one-dimensional cooperative system [4].

A rigorous theory is lacking to calculate macromolecular averages of physical quantities from the interaction energies of all the units considered. Fortunately, however, one can overcome this difficulty with the assumption that the rotation of a skeletal bond is not a continuous process in space but is governed by the existence of discrete rotational isomeric states. This assumption is similar to that made when deriving the properties of internal bond rotations from microwave spectroscopy investigations of rotational bands. For simple molecules such as gaseous ethane, these studies have shown that the internal bond rotation is related to a continuous potential energy

Figure 2 Schematic representation of the mean potential energy of rotation of one skeletal bond about its preceding bond considered as an axis.

function exhibiting minima and energy barriers usually higher than the room-temperature thermal energy [1].

For the sake of simplicity, we show in Figure 2 a schematic representation of the mean potential energy of rotation of one skeletal bond labeled j , which takes into consideration the influence of close neighboring bonds. But such continuous values cannot be introduced as a whole within the framework of statistical physics applied to the description of macromolecular properties. One assumes instead that all potential minima V_1 , V_2 , and V_3 can be assigned to an equilibrium isomeric state of bond rotation; in other words, each energy minimum characterizes a rotational isomer such that the angle variable ϕ is given the discrete values ϕ_1 , ϕ_2 , and ϕ_3 that characterize the minima of Figure 2. Any macromolecular conformation represents successive transitions in space from an isomeric state of one bond to another state of a contiguous bond; a temperature-dependent statistical weight determined from the energies of the corresponding minima thus is assigned to each chain conformation. In this way the rotational isomeric structure of linear macromolecules underlies all physical approaches to the descriptions of the properties of polymeric matter.

3 Polymeric Liquids

3.1 The Basic Importance of Viscoelasticity

A fundamental feature of any polymeric liquid is the elasticity induced by the collective nature of random internal chain motions, which is superimposed on viscous deformation. In the liquid state all chains have the form of coils

that unfold into one another. The transitions of skeletal bonds from some isomeric states to others require jumps over potential energy barriers that occur with temperature-dependent probabilities per unit time. These jumps cause large conformational fluctuations of chains, which make macromolecules essentially entropic systems. The resulting distributions of distances between the ends of any segment and between chain ends are Gaussian regardless of chain length, provided the number of skeletal bonds n is higher than about 20. Because these fluctuations cause a very large array of conformations to be explored per unit time, they induce diffusive motions of translation and rotation of the macromolecules that are characterized by a temperature-dependent correlation time, τ_R .

At about 100 K above the glass transition, a skeletal bond jump occurs every 10^{-9} seconds on average within polymer chains in the liquid state; this time interval is sensitive to restrictions of local volume around skeletal bonds and strongly depends on temperature. For short chains, τ_R is proportional to the number N of units according to Rouse model of internal random chain motions [5]. For polystyrene, with N equal to 35, τ_R is of the order of 10^{-4} seconds about 100 K above the glass transition. More precisely, conformational fluctuations of segments belonging to a chain obey a hierarchy of time-scales: the longer the segments the longer the relaxation times that govern their fluctuations. The limit to these relaxation times is the terminal relaxation time τ_R , associated with the random motions of a chain considered as a whole.

3.2 The Fractional Free Volume

At the nanometer scale volume constraints manifest themselves by friction effects that affect all dynamical properties of polymers even at a macroscopic scale. For each bond, random rotation requires an appropriate local volume to be generated by the rotations of the surrounding units under the influence of thermal energy at temperature T . The concept of fractional free volume has been introduced to account for the shrinkage of this local volume when the polymer temperature, and consequently its thermal energy, is lowered. For this purpose, the specific volume of a polymeric liquid v is considered as the sum of two terms: the first, v_0 , corresponds to the molecular volume defined by electronic orbitals and van der Waals interactions, whereas the second is the free volume $v_f = v - v_0$, which vanishes at the glass transition. The *fractional free volume* is then defined as the ratio $f = v_f/v_0$. The relaxation times associated with volume restrictions and friction effects on bond mobility, and consequently all macromolecular internal relaxation processes, are

proportional to a monomer friction coefficient, ζ_0 , which can be expressed as a function of f as [5]

$$\zeta_0 = \exp\left(\frac{B}{f}\right), \quad (4)$$

This expression was established by Cohen and Turnbull [6]. It is based on the general assumption that any molecule is able to move whenever a free space exceeding a critical volume is created in its immediate vicinity, which is why the coefficient B is of the order of unity. The dependence of f on temperature obeys the linear equation

$$f(T, T_0) = f_0(T_0) + \alpha_f(T - T_0), \quad (5)$$

where $f_0(T_0)$ is the free volume fraction at the chosen reference temperature T_0 and α_f is the coefficient of thermal expansion of the free volume, which is of the order of $3 \times 10^{-4} \text{ K}^{-1}$; comparisons between friction coefficients $\zeta_0(T)$ and $\zeta_0(T_0)$ at temperatures T and T_0 are conveniently made in the form of the ratio $a(T, T_0)$:

$$a(T, T_0) = \frac{\zeta_0(T)}{\zeta_0(T_0)}, \quad (6)$$

or

$$\ln[a(T, T_0)] = - \frac{B(T - T_0)}{f_0(T_0)(T - T_0 + f_0(T_0)/\alpha_f)}. \quad (7)$$

The empirical Williams, Landel, and Ferry (WLF) equation,

$$\log[a(T, T_0)] = - \frac{C_1^0(T - T_0)}{(C_2^0 + T - T_0)}, \quad (8)$$

has been widely used before Eq. (7) was introduced. The coefficients of Eqs. (7) and (8) are related by $C_1^0 = B/(f_0 \ln[10])$ and $C_2^0 = f_0/\alpha_f$. By changing the reference temperature from T_0 to T_1 and combining Eqs. (5) and (7), one finds that the products $C_1^1 C_2^1$ and $C_1^0 C_2^0$ are equal, as well as the differences $T_0 - C_2^0$ and $T_1 - C_2^1$; the former, $T_\infty = T_0 - C_2^0$, is the well-known Vogel temperature (Chapter 4.1) where C_2^0 is of the order of 60 K for most polymers. Numerical values of f_0 and α_f have been tabulated for a large number of polymers; for example, the ratio f_0/B is of the order of 0.030 at the glass transition temperature for more than 30 commonly used polymers [5].

3.3 Viscoelastic Properties

As any liquid, polymer matter under stress flows viscoously via the random motion of its macromolecular components. In addition to this viscous response, the chain structure gives rise to an elastic response, observed

as well on dilute polymer solutions. Except in the glass transition range, such an effect is negligibly small in ordinary liquids where it lasts over 10^{-12} seconds or less, whereas it may last for several days or more in high-molecular-weight polymers. For polymeric liquids, one conveniently observes viscoelasticity by applying a sinusoidal strain characterized by a pulsation ω and a weak amplitude of deformation. The linear response to such a strain is a stress that consists of distinct elastic and viscous components: the former, in phase with the strain and accounting for elasticity, is characterized by the *storage* modulus $G'(\omega\zeta_0/T)$. The latter, 90° out of phase with the strain and accounting for viscous dissipation, is characterized by the *loss* modulus $G''(\omega\zeta_0/T)$. At low enough frequencies, i.e. when $\omega\tau_R < 1$, the amplitude of $G''(\omega\zeta_0/T)$ is much higher than that of $G'(\omega\zeta_0/T)$, whereas both moduli become nearly equal at higher frequencies where $\omega\tau_R > 1$. The ratio between the energies lost and stored during one cycle of strain defines the *loss tangent*, $\tan \delta(\omega) = G''(\omega\zeta_0/T)/G'(\omega\zeta_0/T)$, $\delta(\omega)$ being the loss angle.

The characteristic Eq. (7) leads to a remarkable method of analyzing the frequency–temperature dependence of $G'(\omega\zeta_0/T)$ and $G''(\omega\zeta_0/T)$ responses represented in log–log plots; according to the principle of corresponding states, performing measurements at the frequency ω_0 and at temperature T_0 is tantamount to making observations at the frequency ω' and temperature T' such that $G'[\omega_0\zeta_0(T_0)/T_0] = G'[\omega'\zeta_0(T')/T']$. Correspondingly, ω_0 and ω' frequencies obey the relationship: $\ln(\omega'/\omega_0) = \ln[a(T_0, T')T'/T_0]$; with the assumption that T_0 is higher than T' , then the friction coefficient $\zeta_0(T_0)$ is smaller than the friction coefficient $\zeta_0(T')$, and the ratio $a(T_0, T')T'/T_0$ is smaller than one. Consequently, the experimentally observed curve at temperature T' is shifted as a whole from that observed at temperature T_0 ; the shift toward lower frequencies is defined by the above ratio, applied along the logarithmic frequency scale. Notwithstanding the narrow range of frequencies that can be experimentally explored, this principle makes the determination of experimental values of $G'(\omega\zeta_0/T)$ and $G''(\omega\zeta_0/T)$ possible over a broad range, typically $1-10^8$ rad/s. For example, varying the polymer temperature from 260 to 400 K amounts to shifting the relevant frequency from 10 to 10^4 rad/s [5].

3.4 Temporary Elasticity

Contrary to short chains, long macromolecules in polymeric liquids are subjected to topological restraints. In the frequency spectrum, these induce a splitting of the storage modulus $G'(\omega\zeta_0)$ in two parts separated from each other by a *plateau modulus*, G_N^0 . In the frequency range of the plateau, $\Delta\omega_G$, the proportionality of the

stress to the strain represents an elasticity effect occurring over a time range of 10^{-3} to 1 seconds, which is roughly equal to $1/\Delta\omega_G$ and is characterized by a modulus G_N^0 of the order of 10^5 Pa for most polymers. The *plateau modulus* is interpreted as reflecting a delay that takes place during the stress polymer response to a sudden strain. About 100 K above the glass transition, at high frequencies of about 10^8 rad/s, $G'(\omega\zeta_0)$ and $G''(\omega\zeta_0)$ reflect short-range cooperative rotations of skeletal bonds, which are independent of chain length. At low frequencies of about 1 rad/s, both moduli are governed by a terminal relaxation time specific to long chains, τ_R , such that $\omega\tau_R < 1$.

This relaxation time τ_R is proportional to the local friction coefficient and follows a power law of the number N of units whose exponent is 3.4 (instead of unity for short chains). More precisely, long-range motions of long chains can be schematically depicted as if they were taking place in a tube built from topological restraints (Figure 3); diffusive linear motions of a whole chain within its tube have been described according to the reptation model, proposed by de Gennes [7, 8]. Importantly, these random motions are unrelated to local fluctuations of units that occur within the short segments made up of a characteristic number N_e of monomer units. Depending on the chemical nature of the polymer, N_e ranges from about 100 to 200. In other words, a screening of molecular weight effects takes place along these characteristic segments.

The frequency splitting of the storage modulus $G'(\omega\zeta_0)$ is specific to all high-molecular-weight polymers. Near the glass transition, the cooling rate of the polymer must be compared with the broad spectrum of rates of rearrangements of macromolecular conformations, closely

Figure 3 Mean effects of topological restraints exerted on a chain are schematically depicted as those of a tube (dotted curves) surrounding concatenated segments made up of a characteristic number N_e of monomer units (in between broken lines).

related to chain segment lengths; some relaxation modes characterized by rates shorter than the cooling rate of the polymer do not take place completely so that this truncating effect determines both the spread of the transition and the resulting glassy state.

4 Polymer Transformations

4.1 Partly Crystallized Polymers

Owing to topological restraints and stiffness, long flexible chains cannot completely order even upon slow cooling. In polymers, where crystallites are made up of helical segments arranged side by side, the degree of crystallinity does not exceed 90%, the highest value being reached for polypropylene [9]. Because any long chain may participate in the formation of several contiguous domains, crystallites are connected to one another by soft segments left out of ordered domains.

In most polymers, crystallites appear as lamellae with a 10–15 nm thickness and much broader transverse dimensions. Contrary to the precipitation of crystals in ordinary liquids, the formation of these crystallites necessitates displacements of monomer units to create the structures defined by adjacent helical segments. Helices occur in stereoregular segments built from identical repeating units attached to each other by successive head-to-tail covalent links. In contrast, helices do not form in concatenated segments comprising repeating units with a different chemical nature or built according to tail-to-tail or head-to-head links. This lack of stereoregularity and uniform chain tacticity then prevents crystallization from occurring at all.

As described for other glass-forming systems (Chapter 5.4), crystallization does not begin at the liquidus but below, because the positive interfacial energy of the crystallites must be balanced by their negative bulk free energy, which is an increasing function of the degree of supercooling. The rate of formation of ordered domains also depends on the degree of supercooling: it is equal to zero at the liquidus or at the glass transition and goes through a maximum at intermediate temperatures, hence the need of quenching polymers to prevent them from crystallizing before they undergo the glass transition. Besides, polymer crystallites are also organized on a large scale in the form of spherulites characterized by diameters of the order of 100 μm , which strongly improve mechanical properties. The usual opacity of crystalline polymers thus arises from the presence of these spherulites whose size is much larger than visible light wavelengths.

4.2 Gels

Another important transformation results from the creation of cross-links usually formed at random between long polymer chains from covalent bonds involving foreign

atoms (Chapter 8.8, [10–12]). The process gives rise to a network, called a gel, depicted as an ensemble of segments whose ends are fixed by these covalent cross-links, which prevent chains from flowing and ensures material elasticity instead. A case in point is the network formed by polybutadiene chains $(-\text{CH}_2-\text{HC}=\text{CH}-\text{CH}_2-)_n$ between which covalent bridges are made up of short chains of sulfur atoms. This is an example of the vulcanization process, which is at the roots of the rubber industry where a variety of catalyzing and curing agents are required to achieve optimal chain cross-linking.

As in a liquid, conformational changes of segments still occur, but their amplitudes are necessarily more restricted than those developing within segments in the melt; each segment nevertheless keeps its flexibility, ensuring the collective elasticity of the ensemble. When a gel reversibly undergoes a high deformation, an internal force of retraction exerts itself on the stretched network, but, as noted above, the presence of cross-links prevents the soft polymer from flowing.

5 Glass Transitions and Aging

5.1 α Glass Transition

Some polymers do not crystallize at all because of the strong irregularity of the way in which their monomer units are concatenated. When cooled at sufficiently low temperatures, however, all polymers undergo a glass transition that affects every segment of the network [13]. Contrasting with the macromolecular dynamics observed in the liquid state, no large amplitude random motions of chain segments then occur in the glassy state: skeletal bonds are subjected only to vibrations and torsional oscillations.

In any polymeric liquid there is in fact a hierarchy of timescales characterizing random internal motions of chain segments such that, in the broad spectrum of observed relaxation times, the longest relaxation times are associated with the longest chain segments. Upon cooling, the probabilities of rotational jumps over potential energy barriers strongly diminish, and the free volume, which is thermally activated, also decreases down to the glass transition where it is supposed to vanish. Correspondingly, the increase of the local friction coefficient causes internal chain relaxation times to become longer. The glass transition thus results from the progressive slowing down process of rearrangements of conformations occurring on cooling, whereby macromolecules explore a more and more restricted array of conformations during a given time interval.

According to the space–time hierarchy, which characterizes the internal fluctuations of chains, this process

first affects large amplitude fluctuations involving long segments to give rise to truncated rearrangements; step by step, conformational rearrangements of shorter and shorter segments are then progressively effected until all skeletal bonds get eventually locked. Consequently, the broad spectrum of internal chain relaxation times plays a crucial role in determining the rate of freezing in of the free volume as a function of the cooling rate. In agreement with the fact that the glass transition is not a second-order thermodynamic transition, the lowest minima of the potential energies of rotations of skeletal bonds are not fully occupied below T_g in the frozen-in material.

As determined from the measurements described below, the glass transition of polymers generally takes place over a temperature interval of about 20 °C. As usual, T_g increases with increasing cooling rate. In practice, this shift remains smaller than about 10 °C. Besides, this temperature is higher for polymer networks made up of cross-linked chains than for free chains because segments bounded by cross-links explore a restricted array of conformations and also because the presence of cross-links reduces the local free volume.

In partially crystallized polymers, the glass transition of course involves only those parts of chains left out of crystallites. Although it increases with the degree of crystallinity reflecting a reduction of free volume, it always takes place below the melting temperature of the crystal.

5.2 Secondary Glass Transitions

By cooling a polymer below the α glass transition temperature, one can observe one or two secondary transitions, the first designated by β and the second by γ . They reflect the locking of rotational oscillations of skeletal bond occurring in wells associated with minima of the potential energy of rotations, without any jump occurring above energy barriers. The β transition may also reflect local rearrangements of neighboring side chemical groups attached to chain skeletons. The β glass transition temperature is denoted by T_{s1} . Although the following rule is not general, it is usually close to the difference $T_g - C_{2g}$. Besides, another noteworthy feature of great practical interest resulting from these local rearrangements is that glassy polymers are ductile between T_g and T_{s1} .

5.3 Effects of α to γ Transitions

As for other glass-forming liquids, vitrification in polymeric liquids does not involve any symmetry break, and glass transition temperatures are not strictly defined, but rather depend on the property measured. Variations of second-order thermodynamic properties are frequently investigated as they probe the progressive

Figure 4 Glass transition as detected in measurements of the specific volume (a) and isobaric heat capacity (b), for which typical values are indicated on a weight basis.

slowing down of the amplitude of the skeletal random motion of polymers.

Upon cooling, this process is clearly reflected by the marked decrease of the thermal expansion coefficient α_v (Figure 4) from about 10^{-3} K^{-1} above T_g to one third of this value below T_g . Likewise, a relatively stronger decrease of the isobaric heat capacity of the order of 0.25 J/K/g takes place in a range of about 10 K, without exhibiting any of the features of a second-order phase transition (Figure 4).

Elastic properties show analogous, albeit more complex variations because of a greater sensitivity to chain rearrangements. Polymeric glasses are brittle and their Young moduli may be as high as 10^9 Pa . Upon heating, the Young moduli of different kinds of polymers show slight but clear decreases at the β and γ secondary transitions and then a sharper decrease at the glass transition (Figure 5). For cross-linked chains forming a permanent network, a plateau at about 10^6 Pa is reached at high temperatures, pointing to reversible deformations 1000 times higher in the rubber than in the glass. For long chains, the Young modulus also exhibits first a reversible plateau at about 10^5 Pa , before flow takes place at higher temperatures. A similar evolution is seen for short chains, but the onset of flow is closer to the glass transition.

The glass transition also affects the local friction coefficient introduced in Section 8.7.3.2. By lowering step by step the reference temperature T_0 in Eq. (8), one can choose the glass transition temperature T_g as a reference to determine subsequently the numerical values of the coefficients C_1^g and C_2^g , analogous to the original coefficients C_1^0 and C_2^0 . For a silicone oil, T_g , C_{1g} , and C_{2g} are, for instance, 150, 6.12, and 69 K ($T_\infty = 81 \text{ K}$), respectively, but the same properties for poly(methyl methacrylate) chains are 276, 18.09, and 54 K ($T_\infty = 222 \text{ K}$),

Figure 5 Schematic variations of typical numerical values of elastic moduli shown as a function of temperature. Curve a, polymer network (gel). Curve b, long-chain polymer (number of skeletal bonds higher than 200). Curve c, short-chain polymer. The temperatures of secondary transitions, T_{s1} and T_{s2} , respectively, are shown in addition to the α glass transition temperature T_g .

respectively. As to the fractional free volume f_g/B , it is of the order of 0.025 at T_g for most polymers, whereas the friction coefficient $\zeta_0(T)$ jumps from about 10^{-7} kg/s, at 100 K above the glass transition, to 10^2 kg/s at T_g [7].

Finally, the fact that relaxation timescales become clearly longer than the timescale of experimental measurements when the viscosity becomes higher than 10^{10} – 10^{12} Pa·s has strong effects on the tangent of the loss angle δ (Figure 6), which exhibits a sharp maximum in the glass transition range. Likewise, the smaller peak observed at lower temperatures is associated with a secondary transition.

5.4 Lowering of the Glass Transition

Many solvents of low molecular weight are characterized by a fractional free volume and exhibit glass transitions, like polymers. The addition of good solvents to polymers increases the total free volume of corresponding solutions, whereas the local friction coefficient assigned to monomeric units in each chain diminishes; this effect induces more mobility of macromolecules. At a given temperature, the variation of the fractional free volume f_M with the concentration of the solution is conveniently described by the following equation:

$$f_M(T, T_0, \phi) = \phi f_p(T, T_0) + (1 - \phi) f_s(T, T_0), \quad (9)$$

where f_p and f_s are the fractional free volumes of the polymer and solvent, respectively, and ϕ is the volume fraction of polymer in the solution. By combining Eqs. (2) and (9), one can then obtain the glass transition temperature

Figure 6 Schematic variations of the tangent of the loss angle across the temperature ranges of the α and secondary transitions.

of the solution, $T_{g,M}$, at which the free volume, $f_M(T, T_0, \phi)$, would vanish:

$$T_{g,M} = \frac{(\phi \alpha_p T_{g,p} + (1 - \phi) \alpha_s T_{g,s})}{(\phi \alpha_p + (1 - \phi) \alpha_s)}. \quad (10)$$

In this equation $T_{g,p}$ and $T_{g,s}$ are the glass transition temperatures of the polymer and solvent, respectively, and α_p and α_s similarly the coefficients of thermal expansion of the free volumes in the polymer and solvent.

5.5 Aging

Depending on the heights of potential energy barriers, the probabilities of rotation of skeletal bonds are not necessarily all zero in the glassy state so that local rearrangements can occur over timescales as long as several years. Viscoelastic responses are particularly sensitive to such an aging when a liquid polymer is cooled down to a temperature intermediate between those of the α and β transitions at which it is then kept for a long time Δ . These responses depend on both the temperature and duration Δ of the aging process [14]. The longer the time interval Δ , the larger the number of bonds subjected to local rearrangements that are progressively locked, giving rise to a decrease of the local fluidity. For example, creep affecting a polymer maintained at a fixed temperature takes place over a timescale τ_F that is an increasing function of Δ .

More precisely, the dependence of the creep effect on the correlation of τ_F with Δ closely follows a law of corresponding states according to which performing any creep measurement at a time t , after a time interval of aging Δ , is tantamount to performing creep measurements at a time t' , after a time interval of aging Δ' , such

that $t'/t = \tau_F(\Delta')/\tau_F(\Delta)$. The ratio $\tau_F(\Delta')/\tau_F(\Delta)$ defines a factor of equivalence “creep timescale/time interval of aging,” which is a power law function of Δ' . It is especially striking that this law is observed at any temperature of aging above the β transition; it is characteristic of viscoelastic responses of polymers.

Finally, it must be kept in mind that, in the absence of additives, most polymers can undergo degradation, which develop during long time intervals of aging and give rise to scissions of skeletal bonds. Degradation depends on the polymer chemical structure and can be induced by many factors. Scission of skeletal bonds can, for example, take place under extreme mechanical stress. Besides, phenyl groups attached to chain skeletons are very sensitive to light because of UV-induced formation of radicals, which in turn react with monomer units. Polymers may in addition be sensitive to oxygen, water, heat, and the presence of impurities, which cannot be completely removed during synthesis. A large variety of chemical mechanisms can cause degradation; in most cases, however, their description is beyond the scope of this chapter as they are still not well understood. The expected effects of additives are to prevent oxidation and/or secondary chemical reactions from occurring [15].

6 Polymer Products

6.1 Transparent Materials

High transparency is sought after in many applications. For this purpose, partial crystallization has to be avoided except when macromolecules are made up of units concatenated with a strong irregularity that prevent chain segments from being ordered. Polymethyl methacrylates ($T_g = 380$ K), polycarbonates ($T_g = 413$ K), and polystyrenes ($T_g = 370$ K) are typical polymers usually synthesized for their high transparency; for example, about 90 % of light is transmitted through the 2 mm thick polycarbonate used to make up optical devices for cars. The transparency of polymethyl methacrylates, used to make rigid contact lenses, is higher than that of ordinary glasses with a 92 % light transmission for a 3 mm thickness. Polymethyl methacrylates have good resistance to dilute solutions of acids or of bases and can be exposed to the elements without undergoing chemical damage; their chemical structure is not modified by exposure to UV light.

6.2 Fibers and Films

Many synthetic fibers, like nylon or Kevlar, poly(paraphenylene terephthalamide), in contrast exhibit a high degree of crystallinity; they consist of uniaxially

oriented, hydrogen-bonded crystalline chains; hydrogen bonds ensure mutual sticking of segments. If the tensile strength of Kevlar fibers (3600 MPa) is much lower than those of carbon fibers (7000 MPa), it is comparable with those of pristine silicate fibers, namely, 2.4–5.0 GPa (Chapter 1.6) and, thanks to their lower density, even higher if considered on a weight basis.

Packaging films are obtained from polymers subjected to a biaxial stretching. Consider, for example, the polymer $[-O-CH_2-CH_2-O-CO-C_6H_4-CO-]_m$, which is made up of units containing the distinct ethylene glycol and terephthalate chemical groups whose melting and glass transition temperatures are 538 and 343 K, respectively. The polymer is first lengthwise stretched between these two temperatures at 363 K; then, it is subjected to a lateral stretching at 393 K to give rise to a transparent film with a resulting thickness of 50 μm . The crystallinity then is about 50 %, the residual glassy phase sticking the chains together. In this case there is no light diffusion because the size of crystallites is lower than the wavelengths of visible light.

6.3 Polymeric Foams

One obtains the cellular structure of foams by adding a swelling agent during polymer synthesis; this agent may be water vapor or a chemical product releasing nitrogen or carbon dioxide upon heating. The specific mass of a foam varies from 10 to 100 kg/m^3 to be compared with the typical 10³ kg/m^3 of a bulk polymer. The foam is rigid as long as it is kept at temperatures much lower than T_g . Of interest is the fact that rigid foams exhibit damping of mechanical oscillations and a response to a uniaxial squeeze characterized by both a large compression ratio and a small lateral dilation. Polyurethane foam, a typical example, is synthesized from the reaction of two-functional isocyanate molecules $[O=C=N-R-N=C=O]$ with an alcohol $[OH-R'-OH]$, giving rise to a release of carbon dioxide that originates from the pores; three-dimensional structures are obtained when a three-functional alcohol is used.

6.4 Porous Membranes and Hollow Fibers

Porous membranes represent one of the most remarkable polymer products. Their porosity is achieved with the so-called phase inversion process. In a first step the polymer, poly(ether imide), for example, is diluted in a solvent in *N*-methyl pyrrolidinone such that the glass transition range of the resulting solution is much lower than room temperature. The solution is then quickly immersed in a bath – usually water – which has a strong affinity for the solvent but no affinity at all for the polymer. As a result, the solvent is progressively extracted from the solution,

Figure 7 Porous, hollow Dralon® fiber prepared from polyacrylonitrile $[(C_3H_3N)_n]$.

but the long macromolecular chains prevent them from diffusing rapidly enough to yield a homogeneous polymer phase [12]. The separation takes place instead between a polymer-poor microphase and a water- and solvent-rich microphase on the one hand and between a polymer-rich microphase and a water- and solvent-poor microphase on the other hand. With the appropriate concentration of solvent, the solvent-rich phase gathers as droplets enclosed by walls made up of the concentrated polymeric microphase. Through the extraction of solvent, the polymer concentration increases in the walls whose glass transition temperature rises above room temperature according to Eq. (10). The polymer medium then gets frozen; the remaining solid is made of connected pores with glassy walls. As applied to hollow fibers (Figure 7), the phase inversion process is used to make artificial kidneys consisting of about 8000 fibers put all together in dialysis machines where they are fully compatible with blood. For medical applications, membranes can even be formed with a porosity fitted to the size of bacteria.

6.5 Mineral Particles and Polymer Mixtures

The mechanical properties of polymers can be improved with mineral particles on which the macromolecular chains, connected to one another by chain segments, are partly adsorbed to form a three-dimensional network. The adsorption process of any chain on a particle embedded in a molten polymer results from the formation of an average number of contacts onto the surface equal to the square root of the number of monomer units per chain [12]. Adsorbed chains cannot be easily displaced upon stretching of the mixture, for example; the

stronger the chain-particle adhesion, the stronger, of course, the effect.

Addition to a liquid polymer of mineral particles such as silica or carbon, characterized by a specific area of the order of $150 \text{ m}^2/\text{g}$ resulting from fractal surfaces, enhances the Young modulus in the glassy state by a factor of up to 10. As another example, addition of 40 wt % silica particles to silicone yields a Young modulus of the order of 10^{10} Pa ; conversely, however, stretching at failure may then be reduced by a factor of 10 from 0.3 to 0.03. As to the cohesion of films, one usually enhances it by adding mineral particles whose concentrations remain low enough to ensure transparency.

7 Perspectives

As a convenient way to summarize the tremendous advances made in polymer science, the reader can be reminded that the existence of macromolecules as physical subsystems was recognized only about 80 years ago. New macromolecules keep being created with in particular the aim of improving heat resistance and mechanical properties. As illustrated by the preceding discussion, a deep understanding of polymers is a prerequisite to control the glass transition and, in turn, the properties of the glass state on which particular applications rely.

Particular attention is currently being paid to packaging plastics, aiming, for instance, at reducing food waste, while syntheses of new thin films acting as semipermeable barriers specific to solids, liquids, or gas are in continuous progress. Considering membranes, the stress is laid on a better control of pore size distributions fitted to separation processes such as microfiltration for biomedical research, hyperfiltration for desalination, or ultrafiltration. Besides, perfluorinated ionomer membranes are used as electrolytes for electrochemical processes occurring, for instance, in batteries. Finally, it is worth emphasizing that water-based polymers in the form of colloidal particles dispersed in an aqueous medium, called latexes, will keep their wide variety of applications in paints, adhesives, foams, and coatings.

Introduction to Polymer Chemistry

Oliver Weichold

Institute of Building Materials Research RWTH Aachen University, Aachen, Germany

1 Introduction

With a world production that has almost tripled since 1990 to reach about 335 million tons in 2016, man-made polymers are ubiquitous. They may be clearly visible as in packaging, casings for electronic equipment, toys, and cars or, in contrast, “hidden” in paints, polymer-modified concrete and asphalt, glue joints, or textile blends. The reason for this diversity of uses is that these materials range from liquids to waxes and infusible solids as well as from elastomers to brittle solids. Such a diversity of properties (Table 1) is unique to these materials, even more so since the desired properties can be precisely tailored by a combination of chemistry and processing.

Improperly, these important materials are often called *plastics* or, in German, *artificial material* [Kunststoff]. Epoxies and phenolics do show that they are not necessarily *plastic* in a physical sense, whereas cellulose, spider silk, and DNA indicate that they do not have to be artificial. Hence, they are better termed *polymers* because they are composed of many [πολύς] parts [μέρη]. These are monomers [μόνο, single, and again μέρος, part], which add up as *repeats* to form large, chain-like macromolecules (Chapter 8.7, [6, 7]). The macroscopic properties of polymers originate in the molecular properties of the chains such as the average degree of polymerization ($\bar{X}_n$), composition, geometric factors along the chain, and polarity, which determine the molecular arrangement and cohesion in the solid state. In view of the broad range of properties and structures, it is virtually impossible to provide a set of general design rules for polymers.

Generally, increasing the number of repeat units increases the mechanical properties and the viscosity. The chemical properties of the monomers translate mostly into those of the corresponding polymers, although some water-soluble monomers such as acrylonitrile or *N*-acetylglucosamine can form partially (PAN) or totally water-insoluble polymers (chitosan). The solid-state properties are mostly associated with the glass transition temperature and all effects that act on it also affect the mechanical properties. Beyond that, every field of application operates on their own set of findings and models. To complicate this even further, technical polymers are often blends of two or more homo- or copolymers rather than one homopolymer made from a highly sophisticated monomer. In blends, however, the optimum composition is often determined experimentally.

Polymers can be classified in a number of ways. Here a molecular approach will be adopted through consideration of the mechanism of backbone formation, i.e. the sequence in which monomers assemble into higher-molecular-weight compounds. In a more technical sense, polymers are frequently classified by their macroscopic properties according to the degree of cross-linking. In this respect, polymers are either non-cross-linked *thermoplastics* or cross-linked *thermosets* and *elastomers*. A major feature is that polymer chains are not uniform, but follow a length distribution such as that of Schulz–Flory (Figure 1) commonly observed in industrial processes. The maximum of the distribution represents the average degree of polymerization and yields the molecular weight after multiplication by the mass of the repeat unit. But different properties do not vary in the same way with the degree of polymerization, so it is necessary to distinguish, for instance, weight (w) and viscosity (η) averages, which are found at higher degrees of polymerization.

Another important parameter is the width of the distribution (D), which is characterized by the ratio of weight to number (n) average:

$$D = \frac{\overline{X}_w}{\overline{X}_n} = \frac{\overline{M}_w}{\overline{M}_n}. \tag{1}$$

This is called the dispersity (previously polydispersity or polydispersity index). The Schulz–Flory distribution (Figure 1) is characterized by $D = 2$. As an example, a material produced by free-radical polymerization with an average $\overline{X}_n$ of 2000 contains about 5 and 0.2 ppm of chains with a $\overline{X}_n$ of 20 and 20 000, respectively. In contrast, natural proteins have $D = 1.000$ [unity]. Even modern synthetic methods cannot accomplish such a level of control, however, let alone the precision in controlling the architecture.

Acronyms

ABS acrylonitrile butadiene styrene. Either blend of SAN and NBR or graft copolymerization of acrylonitrile ($\text{CH}_2=\text{CHCN}$) and styrene ($\text{C}_6\text{H}_5-\text{CH}=\text{CH}_2$) onto NBR particles.

Figure 1 Schulz–Flory distribution for polymers with a degree of polymerization $\overline{P}_n = 500$ (light curve) and $\overline{P}_n = 2000$ (dark curve). Positions of the number, weight, and viscosity averages along the distribution indicated for the higher-molecular-weight polymer.

CA	cellulose acetate. Thermoplastic polymers obtained by acetylation of cellulose.	PiB	poly(isobutylene).
CR	chloroprene rubber. Chemically poly(2-chlorobuta-1,3-diene, $\text{CH}_2=\text{CCl}-\text{CH}=\text{CH}_2$), better known as neoprene.	PMMA	poly(methyl methacrylate).
EP	epoxy. Formed by cross-linking epoxy resins, mostly bisphenol A epichlorohydrin pre-polymer, with polyamines.	POM	poly(oxymethylene), $\{\text{CH}_2\text{O}\}_n$.
EPR	(or EPM) ethylene propylene rubber. Random copolymer of ethylene ($\text{CH}_2=\text{CH}_2$) and propylene ($\text{CH}_2=\text{CHCH}_3$).	PP	poly(propylene).
EVA	poly(ethylene-co-vinyl acetate). Vinyl acetate ($\text{CH}_2=\text{CHOCOCH}_3$) content from 0 (pure PE) to 100% (pure PVAc). Low contents blended with PE to increase failure strain; used as hot melt at intermediate contents; rubbery, similar to plasticized PVC beyond 30% vinyl acetate.	PS	poly(styrene).
NBR	nitrile butadiene rubber. Copolymer of acrylonitrile and butadiene ($\text{CH}_2=\text{CH}-\text{CH}=\text{CH}_2$).	PTFE	poly(tetrafluoroethylene), $\{\text{F}_2\text{C}-\text{CF}_2\}_n$.
PA $x(y)$	polyamide. Containing amide bonds $-\text{CO}-\text{NH}-$; x and y , numbers of carbon atoms of the monomer(s), e.g. PA6,6 [poly(hexamethylene adipamide)], PA6 [poly(ϵ -caprolactam)].	PU	polyurethane. Containing the urethane unit $-\text{O}-\text{CO}-\text{NH}-$.
PAN	poly(acrylonitrile).	PVA	poly(vinyl alcohol), $\{\text{CH}_2-\text{CHOH}\}_n$.
PB	poly(butadiene).	PVAc	poly(vinyl acetate), $\{\text{CH}_2-\text{CHOCOCH}_3\}_n$.
PC	polycarbonate. Containing carbonate unit $-\text{O}-\text{CO}-\text{O}-$, but usually referring to poly(oxy-carbonyloxy-1,4-phenyleneisopropylidene-1,4-phenylene), the condensation product of phosgene and bisphenol A.	PVB	poly(vinyl butyral).
PDMS	poly(dimethylsiloxane). Made from either dichlorodimethylsilane ($\text{Cl}_2\text{Si}(\text{CH}_3)_2$) by polycondensation or cyclic dimethylsiloxanes ($\{\text{Si}(\text{CH}_3)_2\text{O}\}_n$ with $n = 5, 6$) by ring-opening polymerization.	PVC	poly(vinyl chloride), $\{\text{CH}_2-\text{CHCl}\}_n$; abbreviated as PVC-P [P = plasticized] and PVC-U [U = unplasticized] or as S-PVC [S = suspension polymerization] and M-PVC [M = bulk polymerization].
PE-HD	high-density poly(ethylene).	SAN	copolymer of styrene and acrylonitrile, similar to PS in properties, but with $T_g > 100^\circ\text{C}$.
PE-LD	low-density poly(ethylene).	SBR	styrene butadiene rubber.
PEO	poly(ethylene oxide), $\text{HO}[\text{CH}_2-\text{CH}_2-\text{O}]_n\text{H}$; low-molecular-weight types sometimes called poly(ethylene glycol) (PEG) because of chemical kinship with ethylene glycol $\text{HO}-\text{CH}_2-\text{CH}_2-\text{OH}$.		
PES	polyethersulfone, a class of high-performance polymers of the general type $\{\text{C}_6\text{H}_4-\text{O}-\text{C}_6\text{H}_4-\text{SO}_2\}_n$.		
PET	poly(ethylene terephthalate), $\{\text{OC}-\text{C}_6\text{H}_4-\text{CH}_2-\text{CH}_2-\text{O}\}_n$. Most prominent member of the polyester family mainly used for beverage bottles and in textile industry where it is abbreviated PES despite the potential mix-up with polyethersulfone.		

2 Polymer Synthesis

The formation of polymers from small molecules can proceed by two principal mechanisms, namely, step and chain growth (Figure 2). Which of these two mechanisms the synthesis follows is solely determined by the type of monomers; only very few polymers can be synthesized by both mechanisms, albeit from different monomers. Polymers formed by chain-growth reactions can be thermoplastics (e.g. PMMA) or thermosets (e.g. resin-based dental cements). Likewise typical step-growth polymers can be either thermoplastics (e.g. PA6,6) or thermosets (e.g. epoxy).

2.1 Chain-Growth Polymerization

Chain growth is characterized by a single *active* site normally at the end of the chain, to which monomers add, just like pearls are threaded on a string. The formation of the polymer only occurs at these sites and only while the site is active. Once the active site is lost, polymerization can continue only if a new one forms. As a consequence, chain growth can be divided into the three main stages of *initiation* [generation of an active site], *propagation* [chain growth], and *termination* [loss of active site]. This mechanism most commonly applies to unsaturated monomers such as propylene or styrene and will be explained using the example of *free-radical* polymerization.

Initiation begins with the decomposition of suitable molecules called initiators, abbreviated as Ini_2 . Common

Figure 2 Schematic representation of the chain-growth (top) and step-growth (bottom) mechanisms. ⊗ indicates the active site in the chain-growth mechanism.

Initiation

Propagation

Termination

Figure 3 The three main phases of free-radical polymerization illustrated by PVC with AIBN initiator.

ones are 2,2'-azobis(*iso*-butyronitrile), AIBN, dibenzoyl peroxide, DBPO, and potassium persulfate ($\text{K}_2\text{S}_2\text{O}_8$, KPS). The decomposition of initiators leads to the formation of radicals, which then add to the monomer (Figure 3) to create the active site of the chain, which is the terminal atom bearing an unpaired electron: this is why the process is termed *free-radical* polymerization. Through propagation, monomers add to the active site, thereby increasing the number of repeat units in the chain and building up molecular weight. The regular mode of termination is either *combination*, in which two active sites combine to form a chain of double molecular weight, or *disproportionation*, which is the transfer of a hydrogen atom from one chain to the active site of a second chain. This exchange leaves one polymer with an unsaturated

end and the other with a saturated end, so it does not modify the molecular weight of the chains. In this context, termination always refers to individual chains and not to the reaction as a whole. Macroscopically observable polymerization thus proceeds as long as the initiation process supplies new radicals.

At low conversion rates, a steady state is obtained upon propagation such that the rates of initiation and termination are equal, i.e. the number of active sites is constant. The resulting molecular weight then is inversely proportional to both the rate of polymerization and the initiator concentration. As a result, increasing temperature or adding more initiators results in shorter chains.

Radicals are highly reactive species so they can undergo a number of side reactions. Depending on experimental conditions (e.g. temperature, solvent quality), the initiator radicals may recombine without starting a chain, in which case radical sites are annihilated as termination reactions also do. On the other hand, *transfer* reactions such as removal of a H atom by reaction of a radical with a C–H bond (i.e. H-abstraction) do preserve the unpaired electron. Provided the new species is of sufficient reactivity, it can serve as an active site to keep polymerization going. Transfer can involve any compound present in the reaction mixture, including solvent, monomer, and polymer. The latter, however, causes branching. When uncontrolled, transfer reactions usually have negative effects on polymerization such as lower molecular weight and conversion or increased branching. On the other hand, transfer reactions are sometimes deliberately induced by the addition of transfer agents in order to control the molecular weight or afford polymers with functional chain ends. Examples are fluorotelomer alcohols (FTOH), for instance, used in fire-protecting foams and stain-resistant coatings or in the production of synthetic rubber to which thiols are added to control molecular weight.

Chain-growth polymerization, and especially free-radical polymerization, is not limited to single monomers. In fact,

Figure 4 The greater variety of molecular architectures obtained by binary copolymerization with respect to homopolymerization.

a large number of industrial materials are copolymers made from monomer mixtures. Because the molecular weight and degree of branching of homopolymers are difficult to control, copolymers have the major advantage of offering an enormous variety of possibilities to tune macroscopic properties through control of not only the

Figure 5 Terminal model of binary copolymerization. The four possible combinations are characterized by rate constants, which are then combined to reactivity ratios r indicating the tendency of an active site for homopolymerization vs copolymerization. Polymer chain symbolized by “~.”

polymer composition but also of the molecular architecture (Figure 4).

Copolymerization of monomer mixtures under chain-growth conditions proceeds like homopolymerization. In a mixture of two monomers, M_1 and M_2 , however, the active site formed in the previous step from M_1 or M_2 can now add to the same kind of monomer or to the other. This approach, which only considers the rate-determining chain ends, is called the terminal model and operates on four kinetic constants (Figure 5). These are combined to two reactivity ratios $r_{1,2}$, which express the tendency of a chain end to form homo- or heterodiads, diad in this context referring to two consecutive repeat units. The values of r_1 and r_2 relative to each other determine the architecture of the resulting polymer (Table 2).

As a result of improved properties, a large number of modern polymer materials are copolymers. The SAN copolymer of styrene and acrylonitrile, for instance, exhibits a higher strength and a better scratch and crazing

Table 2 Values of the reactivity ratios $r_{1,2}$ and resulting polymer architecture.

Ratios	Description	Example
$r_1 = r_2 = 1$	Ideal statistical copolymerization	Acrylamide/acrylonitrile $r_1 = 1.08, r_2 = 0.97$
$r_1 = r_2 = 0$	Strict alternating copolymerization	Maleic anhydride/vinyl acetate $r_1 = 0, r_2 = 0.019$
$r_1, r_2 < 1$	Statistical copolymerization, but polymer composition changes with reaction time	Styrene/acrylonitrile (SAN) $r_1 = 0.29, r_2 = 0.02$
$r_1 < 1, r_2 > 1$	M_2 blocks interrupted by short M_1 blocks	Styrene/1,4-butadiene (SBR) $r_1 = 0.83, r_2 = 1.83$
$r_1, r_2 > 1$	Long alternating blocks of M_1 and M_2	Not observed in radical polymerization

Figure 6 The three principal stereoisomers made from vinyl monomers with a single substituent (using PP as an example). Wedged and dashed bonds pointing to substituents in front of and behind the plane, respectively.

resistance than PS. Like PS, however, SAN is brittle, but it can be modified with a butadiene acrylonitrile copolymer to form ABS, a *terpolymer alloy*, which shows an improved impact resistance. Likewise, numerous modern synthetic rubbers are copolymers such as ethylene vinyl acetate (EVA), ethylene propylene (EPR), styrene butadiene (SBR), and acrylonitrile butadiene (nitrile rubber, NBR).

With very few exceptions (e.g. ethylene), the most common monomers used in radical polymerization carry a single substituent at the double bond. Upon polymerization the geometry at the terminal carbon changes from trigonal (the active site) to tetragonal (the polymer chain) so that two consecutive substituents can end up on the same or different sides of the chain. The phenomenon is called *tacticity*. It gives rise to three principal stereoisomers (Figure 6) depending on whether all substituents are on the same side [*isotactic*], on strictly alternating sides [*syndiotactic*], and are randomly distributed between the sides [*atactic*]. In free-radical polymerization, the stereochemistry cannot be controlled, so such polymers are highly atactic. Tacticity is controlled through coordination polymerization with transition metal catalysts, often based on titanium or zirconium (the Ziegler–Natta catalysts), whose metal center determines a predefined coordination orientation for the monomer and chain.

Such a molecular engineering has been an outstanding achievement to control material properties through

Table 3 Macroscopic properties of the stereoisomers of poly(propylene) and poly(styrene).

Polymer	Stereoisomer	T_g (°C)	T_m (°C)	ρ (g/cm ³)
Poly (propylene) ^a	Isotactic, crystalline	−12	163	0.92
	Syndiotactic, crystalline	−4	130	0.95
	Atactic, amorphous	−7	—	0.85
Poly(styrene)	Isotactic, crystalline	—	240	1.08
	Atactic, amorphous	95	—	1.04

^a Thermal data for polypropylene [4].

stereochemistry. For example, atactic PP and PS are amorphous thermoplastics with moderate softening temperatures, whereas their isotactic isomers are semicrystalline thermoplastics with considerably higher melting points (Table 3).

The chain-growth mechanism is, however, not limited to free-radical polymerization of unsaturated monomers. It is also followed by anionic and cationic polymerization of olefins; a commercial example of the latter is the production of butyl rubber, which is prepared by cationic polymerization of isoprene-containing mixtures between −40 and −100 °C in hexane. In addition, ring-opening polymerizations of cyclic monomers such as ϵ -caprolactam to PA6 and ethylene oxide to poly(ethylene oxide) proceed via successive addition of monomers to an active site – hence a chain-growth mechanism – although the resulting polymers have the appearance of step-growth products (Figure 7).

2.2 Step-Growth Polymerization

One fundamental difference between step and chain growth is that the former does not involve active sites in the way chain-growth polymerization does. In a mixture of molecules bearing more than one functional group, reaction can occur between any two suitable molecules to produce first dimers and then trimers, tetramers, and so on. If the functional groups are denoted by A and

Figure 7 Chain-growth mechanism exemplified by the ring-opening polymerization of PA6 from ϵ -caprolactam.

B, the assumption is that both A and B react only unlike units. Thus, monomers of the sort AB, such as lactic acid or amino acids, form polymers of the type $-AB-AB-AB-$, where “-” denotes the newly formed bond. In contrast, mixtures of AA (e.g. diols) and BB (e.g. diacids or diisocyanates) form polymers of the type $-AA-BB-AA-$. These two polyamides may seem similar, but the small differences between their molecular structures do cause the noticeable differences in macroscopic properties apparent in Table 1 between PA6 (made from the AB precursor ϵ -caprolactam) and PA6,6 (made from 1,6-diaminohexane and adipic acid).

A second fundamental difference between chain and step growth is that there is no termination in the latter. The chains can theoretically keep growing until no unreacted functional groups A and B remain in solution, although this is not observed in practice. Owing to the following kinetic scheme, the correlation between the conversion p and the degree of polymerization $\bar{X}_n$ is rather simple:

$$\bar{X}_n = \frac{1}{1-p} \quad \text{with } p = \frac{N_0 - N_t}{N_0}, \quad (2)$$

where N is the number of unreacted functional groups at the beginning ($t = 0$) and at time t during the reaction. This equation was first proposed by W. Carothers in the 1930s [8]. It clearly indicates that high-molecular-weight polymers are obtained only at high conversion in step-growth polymerization (Figure 8). For example, PA6,6 fibers require $\bar{X}_n > 110$ for sufficient mechanical strength, which corresponds to $p > 99\%$. Conversions of this extent without side reactions are a real challenge

Figure 8 Step-growth polymerization as described by the Carothers equation (black line) for the average degree of polymerization. High values obtained only at high conversions. Significant decreases caused by even slight deviations from the ideal 1:1 stoichiometry (gray lines).

for the toolbox of preparative chemists. It is therefore not surprising that until now, only four known reactions yield high-molecular-weight polymers under step-growth conditions. These are the *Schotten–Baumann* reaction, a polycondensation at the oil–water interface mainly used as a show experiment; the dehydration of salts, used for the preparation of PA x,y polyamides; transesterification used for the preparation of polyesters; and the polyaddition of diols to diisocyanates used for the preparation of polyurethanes.

Actually high-molecular-weight polymers are not always wanted, since they are difficult to process, whereas low-molecular-weight compounds might not exhibit the desired mechanical properties. A mechanism to control the degree of polymerization is therefore desirable. Rapid cooling allows the polymerization to be stopped at any given point, but a more elegant control arises from the fact that Eq. (2) is only valid for mixtures with an exact 1:1 stoichiometry. Intentional or unintentional deviations from the ideal ratio automatically cause a decrease in the degree of polymerization, since all chains will ultimately have the same type of end group. This situation is described by the modified Carothers equation:

$$\bar{X}_n = \frac{1+r}{1+r-2rp}. \quad (3)$$

where r , the molar ratio of monomers, needs to be lower than 1 (Figure 8). One may thus obtain the desired molecular weight by properly adjusting r and allowing the reaction to end naturally.

One achieves the opposite effect, namely, increasing the molecular weight, by adding monomers with more than two functional groups to the reaction mixture. By introducing an average functionality f_{av} ,

$$f_{av} = \frac{\sum n_i f_i}{\sum f_i}, \quad (4)$$

where n_i is the number of moles of the reactant with the functionality f_i , one rewrites the Carothers Eq. (2) as

$$\bar{X}_n = \frac{2}{2 - pf_{av}}. \quad (5)$$

For example, a mixture for preparing an aliphatic polyester containing 1 mol of adipic acid, 0.8 mol of ethylene glycol, and 0.2 mol of glycerol ($f_i = 3$) has $f_{av} = 2.1$ and reaches $\bar{X}_n = 400$ at 95% conversion, whereas a 1:1 mixture of adipic acid and ethylene glycol would still be at $\bar{X}_n = 20$. From Eq. (5) it follows that the degree of polymerization becomes infinite when $pf_{av} = 2$. At this point the polymer becomes a gel, i.e. it forms a quasi-infinite network. The corresponding conversion limit can be written as

$$p_G = \frac{2}{f_{av}}. \quad (6)$$

Figure 9 Preparation of poly(vinyl acetate) and subsequent polymer analogous transformations to poly(vinyl alcohol) and poly(vinyl butyral).

Careful experiments have shown that Eq. (6) slightly overestimates the conversion required for gelation because those macromolecules having an X_n value higher than the average value of the mixture gel earlier.

Stepwise growth of the chains is the underlying mechanism in both polycondensation and polyaddition. The difference between them is that small molecules such as water or hydrochloric acid are formed in the former, which need to be removed from the reaction mixture to shift the equilibrium in the right direction. Both polycondensation and polyaddition are important technological processes: a number of commodities such as epoxy, phenolic, melamine, urea-formaldehyde resins, and polyurethanes are prepared by polyaddition, whereas most high-performance polymers such as polyethersulfone (PES) ($T_g = 225^\circ\text{C}$), polyether ether ketone (PEEK) ($T_g = 150^\circ\text{C}$), polyamide (decomposition temperature in air $>550^\circ\text{C}$), and polybenzimidazole (PBI) ($T_g = 425^\circ\text{C}$) are made by polycondensation.

2.3 Polymer Analogous Reactions

When designing polymers for specific applications, the preeminent way is to assemble the chains from suitable low-molecular-weight monomers with one of the two aforementioned mechanisms. There is a third way to tune properties, however, namely, through conversion of one polymer into a second one without deliberate alteration of the degree of polymerization. The most prominent examples of these *polymer analogous* reactions (Figure 9) are the preparation of poly(vinyl alcohol) (PVA) from poly(vinyl acetate) (PVAc), the conversion of PVA to poly(vinyl butyral) (PVB), and the preparation of the cellulose acetate (CA) and cellulose nitrate families.

The reasons for making use of these reactions are manifold. In the case of PVA and PVB, the polymers cannot be prepared by direct polymerization. Vinyl alcohol, the hypothetical monomer of PVA, tautomerizes to acetaldehyde with an equilibrium constant $K \approx 10^{-7}$, whereas PVB cannot be made by direct polymerization of a particular monomer.

Reactions with functional groups at the polymer backbone can be slower or faster than with similar groups in low-molecular-weight compounds. An increased rate is usually the result of neighboring group participation and is, for instance, observed in the alkaline hydrolysis of PVAc, which leads to a pronounced blockiness of the resulting PVA–PVAc copolymer; the acidic hydrolysis does not show this effect and gives rise to a random copolymer instead. More frequently, however, polymer analogous reactions suffer from retardation. In order to react, the reactants have to find and approach each other on a defined trajectory. Polymers usually have low diffusion coefficients in solution and increase the viscosity of the reaction medium, which are both detrimental to the reaction rate. In addition, polymers in solution adopt coiled conformations so that only the outermost functional groups of the backbone are easily accessible. The backbone, which commonly carries substituents at every other carbon atom, also imposes a considerable steric constraint on the reaction trajectory.

3 Polymerization Processes

For polymerization processes, the primary issue is interestingly not chemical, but technical, concerning the continuous or batch nature of the production [9]. The former

is economical only for large-scale commodities or designated specialties, but not suitable for all polymerization mechanisms and/or all monomers. As a matter of fact, PS, SAN, and PMMA molding compounds are frequently produced continuously [10], whereas most other processes are run semi-batchwise.

A second issue is whether processes should be single- or multiphase. The former include bulk, melt, and solution, whereas the latter are realized in the form of emulsions or suspensions. Since most of the monomers used in radical polymerization are liquid, the simplest way to process them is in the bulk, i.e. without any diluting agent. Under these conditions, the volume concentration of the monomer is maximized so that high initial rates of polymerization are achieved. Bulk polymerization can proceed in two distinct ways: if the polymer is insoluble in the monomer, it will precipitate once the limiting molecular weight is reached and polymerization continues in the remaining liquid phase. This is, for instance, observed for the bulk polymerization of vinyl chloride. If the polymer is soluble, the liquid phase becomes increasingly viscous upon polymerization owing to the formation of high-molecular-weight products. As a consequence, the steady-state conditions quickly cease to be respected. The rate of polymerization increases already at fairly low conversions, instead of decreasing as expected for continued initiator and monomer consumption (Figure 10).

This *gel* or *Trommsdorff–Norrish* effect is caused by the high viscosity of the mixture, which impairs the bimolecular termination of the growing chains [11]. Further polymerization deprives the mixture of more and more monomer, however, which reduces the plasticizing effect of the monomer. If the glass transition temperature of the polymer is higher than the reaction temperature, the mixture becomes glassy and polymerization stops,

leaving unreacted monomer. These drawbacks, along with trace amounts of harmful monomers in the product, the tendency to form high-viscosity gels, and also difficult heat control, are the reasons why radical polymerization in the bulk is rare in industrial production. One of the few exceptions is the production of high-quality acrylic glass sheets in a process called batch-cell bulk polymerization, where bulk polymerization is the method of choice, followed by a posttreatment of the sheets at temperatures above T_g to reduce the residual monomer content.

Step-growth polymerization such as polycondensation is in contrast frequently run in the melt because they are – with few exceptions – slower than radical polymerization. A common process to produce the PET used in the textile industry is melt condensation at about 280 °C in vacuum. As outlined above, high-molecular-weight polymers are only formed at high conversions in step-growth reactions, so the mixture remains at a low viscosity throughout most of the process.

Another important feature of radical polymerization is its highly exothermic nature, except in the cases of incomplete conversions and residual monomers. Bulk polymerization thus suffers from problematic heat dissipation, which could ultimately cause thermal runaway, particularly at larger scales. The simplest way to circumvent the difficulty is to dilute the reaction mixture with an inert solvent that dissolves both monomers and polymer, but a potential side effect then is chain transfer to the solvent, which lowers the degree of polymerization. This procedure is actually the most common in the laboratory, but it is not much adopted in industry because of safety and environmental issues raised by organic solvents. An exception is PVAc, which is frequently prepared in solution; at the end of the reaction, then either the solvent

Figure 10 Rate of polymerization as a function of monomer conversion (a) at a given temperature (e.g. horizontal line in b) and temperature dependence of the point at which the reaction mixture becomes glassy and polymerization stops (b).

is recovered and reused, or the solution is sold as it is (e.g. for solvent-based adhesives).

For environmental reasons, the most desirable medium to run polymerizations is water, which has the added advantage of having an enormous heat capacity. Some monomers such as epoxides and isocyanates are sensitive to water, whereas the most common monomers for radical polymerization are immiscible with it (e.g. ethylene, propylene, styrene, methyl methacrylate, or vinyl chloride). There are then two possibilities for biphasic processing.

In *suspension polymerization*, a monomer–water mixture is vigorously stirred to break up the monomer phase into small, 0.1–5 mm-sized droplets. With monomer-soluble initiators, polymerization begins within the droplets and proceeds as in the bulk without raising heat-dissipation problems thanks to the small volume of the droplets. Since the polymer particles are not stabilized, they usually sediment when stirring is stopped and can then be easily removed. The process is frequently used for the production of poly(vinyl chloride) (PVC), sometimes called S-PVC, and poly(tetrafluoroethylene).

In *emulsion polymerization*, the initiator needs to be soluble in water. A surfactant or protective colloid is added to produce an enormous number ($\sim 10^{21}$) of 4–5 nm micelles and a much lower number ($\sim 10^{14}$) of 1 μm monomer droplets. The latter act as reservoirs from which polymerization is fed “on demand” as the reaction progresses. Initiation occurs in the aqueous phase, from which the growing chains migrate almost exclusively into the micelles whose number overwhelms that of the monomer droplets. For the same reason, the likelihood of two growing chains migrating into the same droplet is rather low, so bimolecular termination within the droplets is quite rare. As a result, polymers prepared by emulsion polymerization can have unusually high molecular weights. The final surfactant-stabilized polymer emulsion is called latex and is frequently sold as is as a basis, for instance, for paints.

4 The Solid State

4.1 The Glass Transition

The long chains of polymers with their vast number of conformations and broad distribution of chain lengths generally make crystallization difficult. For amorphous polymers, the glass transition is the only transformation through which changes in mechanical properties have important implications in that T_g marks either the upper service temperature for amorphous thermoplastics or, in contrast, the lower one for elastomers.

In polymer chemistry, the glass transition temperature is defined as the onset of large-scale cooperative motion

of chain segments [12]. A number of kinetic or equilibrium theories have been developed to account for the glass transition and the factors that influence it. The most widely used is the free-volume theory of Williams, Landel, and Ferry [13]. Actually the free volume V_f is not the unoccupied space that is inevitably left in an ordered or random packing of molecules. It is rather the space additionally occupied by molecules as a result of their thermal motion [9], whose amplitude increases with temperature as related to the coefficient of thermal expansion. For most amorphous polymers, the free-volume fraction $V_f/\bar{V}$, where $\bar{V}$ is the specific volume, has a constant value of 0.025 [12] when a glass forms upon cooling at the universal viscosity of 10^{12} Pa.s (Chapter 4.1). In other words, this fraction is the limit at which the large-scale cooperative motion of chain segments sets in upon heating or subsides upon cooling.

4.2 Structural Control of the Glass Transition

In light of the relation between T_g and molecular motion within the chain, it is evident that all factors influencing the mobility also influence T_g . The most important are (i) molecular weight; (ii) chain flexibility; (iii) geometric factors along the chain such as symmetry, branching, and side chains; (iv) attractive forces between chains such as polarity, cross-linking, and crystallinity; and (v) external factors such as plasticization, pressure, and rate of testing.

A simple example is the increase of T_g with molecular weight. Since they are only bound only on one side, chain ends are more mobile than internal chain segments and, thus, contribute more to the free volume. As the molecular weight decreases for a given polymer, the ratio of chain ends to internal segments increases, which results in a lower T_g . The effect is stronger at lower molecular weights, however, so T_g ultimately reaches an upper limit. Fox and Flory relied on such considerations to obtain the following equation:

$$T_g = T_g^\infty - \frac{K}{\bar{M}_n}, \quad (7)$$

where T_g^∞ is the glass transition temperature of chains of infinite length in Kelvin and K is a constant related to the free volume [14, 15]. For poly(styrene) (PS), the values $T_g^\infty = 373$ K and $K = 2 \times 10^5$ K g/mol have been found [12]. In light of Eq. (7), the T_g data presented in Table 1 can only be seen as guides. Some of discrepant T_g values reported in the literature might actually result from disregard of the actual molecular weights and the structure of the polymers.

Another effect on T_g is that of chain flexibility, which correlates with the rotational barrier about covalent

Table 4 Influence of chain flexibility on T_g [3].

Polymer	T_g (°C)
$\left[\begin{array}{c} \text{CH}_3 \\ \\ \text{---Si---O---} \\ \\ \text{CH}_3 \end{array} \right]_n$	-123
$\left[\text{CH}_2\text{---CH}_2 \right]_n$	-78
$\left[\text{---} \langle \text{C}_6\text{H}_4 \rangle \text{---O---} \langle \text{C}_6\text{H}_4 \rangle \text{---SO}_2 \text{---} \right]_n$	250

bonds in the polymer backbone, in particular with the energy differences between the rotational isomers of *gauche* and *trans* conformations. This effect is particularly pronounced in poly(dimethylsiloxanes), owing to the large mean Si–O–Si bond angle and broad bond angle distribution of 105–180°, and in poly(ethylene), in view of its slender chain (Table 4). In contrast, aromatic rings in the polymer backbone increase the rotational barrier and give rise to high- T_g materials such as PES.

A more pronounced influence on T_g is exerted by geometric factors along the chain. Symmetry is the simplest of these factors although its effects may be convoluted. The T_g of -10 °C of poly(propylene) $\text{CH}_2=\text{CHCH}_3$ (PP), for instance, compare with the value of -70 °C of poly(*iso*-butylene) $\text{CH}_2=\text{C}(\text{CH}_3)_2$ (PiB). Similar differences are observed for PVC $\text{CH}_2=\text{CHCl}$, $T_g = 98$ °C and poly(1,1-dichloroethylene) $\text{CH}_2=\text{CCl}_2$, $T_g = -18$ °C, as well as for poly(vinyl fluoride) $\text{CH}_2=\text{CHF}$, $T_g = 41$ °C, and poly(1,1-difluoroethylene) $\text{CH}_2=\text{CF}_2$, $T_g = -35$ °C [2]. In these cases, one could surmise that an additional substituent in the chain would increase rotational barriers, and T_g by the presence of more unfavorable *gauche* conformations. But the additional substituent requires first of all more space, thereby forcing the chain to adopt a more open structure, which increases the free volume and results instead in a lower T_g .

The symmetry effect becomes more pronounced as substituents become larger, as in the case of polymers exhibiting branching or side chains. Large, flexible branches that can originate from chain transfer to the polymer during radical polymerizations force the chains further apart, which increases the free volume and lowers T_g . The effect of side chains can be easily observed when comparing a series of methacrylates (Table 5). Aliphatic side chains are rather flexible, so increasing their lengths gives rise to lower glass transition temperatures. In contrast, rigid or bulky substituents such as phenyl groups (C_6H_5) hamper cooperative motion and thus raise T_g .

Table 5 Effect of side chains on T_g for a series of methacrylates [2].

General formula	R	T_g (°C)
$\left[\begin{array}{c} \text{CH}_3 \\ \\ \text{H}_2\text{C} \text{---} \text{C} \text{---} \\ \\ \text{C=O} \\ \\ \text{O} \\ \\ \text{R} \end{array} \right]_n$	CH_3	106
	$(\text{CH}_2)_3\text{CH}_3$	20
	$(\text{CH}_2)_7\text{CH}_3$	-20
	C_6H_5	110

Other complications result from the fact that the free volume claimed by a single chain is not fully determined by the conformations adopted in the course of cooperative motion. The constraints imposed by the neighboring chains must also be taken into account. Chains in close vicinity, for instance, experience attractive forces, which are at least one if not two orders of magnitude weaker than the covalent C–C and C–O bonds that hold together the polymer backbone. Such non-covalent attractive effects may be van der Waals forces (mainly effective in simple polymers such as PE and PP), dipole–dipole interactions, or hydrogen bonding. For high-molecular-weight polymers, attractive forces between chains can act at a large number of positions along the chains. Even though such interactions are individually weak, their sum may be considerable. This *cooperative effect* is, for instance, the reason why polymers decompose on heating under normal conditions before they can separate into individual molecules in the gas phase.

Clearly, all factors that increase attractive forces between chains and impede chain separation cause a reduction of the free volume and an increase in T_g . In the pair PP/PVC, where the steric demand of the substituents are comparable, T_g increases from -10 °C for PP to +87 °C for PVC because of the increased polarization of the C–X (X = CH_3 , Cl) bond. Likewise, in the pair PS/poly(4-vinylpyridine), T_g increases from 95 °C for PS to 142 °C for poly(4-vinylpyridine). Another factor impeding chain separation is cross-linking, i.e. chains covalently bound to one another by short units to form a 3-D network. This factor prevents the chains from moving too far apart and also shortens the flexible parts, since cooperative motion is only possible for segments between the cross-links. For slightly cross-linked systems such as vulcanized rubbers, the empirical correlation

$$T_g = T_g^0 + \frac{3.9 \cdot 10^4}{\overline{M}_c} \quad (8)$$

has been found [12], where T_g^0 is the glass transition temperature of the non-cross-linked polymer in K and $\overline{M}_c$ is the number average molecular weight between the

cross-links. Although only properly applicable to low cross-linking densities, Eq. (8) would clearly yield irrelevant T_g values as the chain length between the cross-links gets smaller. This is indeed observed in highly cross-linked systems such as epoxies, for which no T_g can be detected.

4.3 Semicrystalline Polymers

The preceding discussion applies only to fully amorphous polymers. For example, straight-chain aliphatic substituents remain so up to a length of about 14 carbon atoms. Longer chains tend to crystallize [16] because the enthalpy released when crystalline domains form in side chains overcomes the entropic effects of conformational freedom of the backbone. In addition, crystallization increases the intermolecular attractive forces, which in total retards the onset of cooperative motion [16].

In semicrystalline polymers, crystalline domains act as physical cross-links with the same effect on T_g as covalent cross-links. Semicrystalline polymers additionally exhibit a melting temperature T_m , which thus marks their upper service temperature. It turns out that some of the factors influencing T_g such as intermolecular attractive forces also affect T_m in the same direction. There is to date no known physical correlation between T_g and T_m , which seems unlikely to exist since melting is a true first-order transition, whereas the glass transition is not. However, when plotting T_g vs T_m , most linear homopolymers are found between a ratio $T_g/T_m = 0.5 \dots 0.8$ (Figure 11). That is, when using one of the above mechanisms to tune the T_g of a polymer, T_m is most likely also altered in the same direction, giving rise to either high $T_g - T_m$ materials or low $T_g - T_m$ materials [11]. One way to gain independent control over T_g and T_m is copolymerization.

4.4 Plasticization

Finally, an industrially rather important concept for lowering T_g is plasticization. The most prominent example is PVC, which turns from a hard, brittle material into artificial leather upon addition of up to 40 wt % of plasticizers. Plasticizers are usually high-boiling, low-molecular-weight liquids such as bis(2-ethylhexyl) phthalate (DOP), which are miscible with the polymer, although short-chain oligomers have been used to reduce migration of the plasticizer [17]. The plasticizing effect can be described in a number of ways: the plasticizer can be seen as a solvent, which separates the chains and reduces the intermolecular attractive forces – similar to the action of the monomer in bulk polymerization. Alternatively, the mixture of polymer and plasticizer can be seen as a blend, for which the T_g can be estimated in a first approximation by Fox' additivity rule:

Figure 11 Relation between T_g and T_m for selected polymers, most linear homopolymers having a ratio T_g/T_m ranging from 0.5 to 0.8. Source: Data from Table 1 and [2]. Rubbers unvulcanized. The dashed lines: 0 °C.

$$\frac{1}{T_{g,m}} = \frac{w}{T_g} + \frac{w_1}{T_{g,l}}, \quad (9)$$

where $T_{g,m}$ and $T_{g,l}$ are the glass transition temperatures of the mixture and the plasticizer in K and w , w_1 are the weight fractions of the polymer and the plasticizer. A practical example of reversible plasticization are non-iron shirts made from nylon (PA6,6) for which the considerable amount of water taken up during washing lowers T_g below ambient temperature. When hung up wet, the weight stretches the fibers and removes creases. During drying, the T_g shifts back to higher temperatures and fixes the smooth appearance.

5 Perspectives

Compared with wood, bricks, alloys, and mortar, polymers are rather young engineering materials. Since the beginning of their large-scale industrial production and widespread use in the 1950s, polymer chemistry and processing has improved tremendously. A number of teething problems such as poor impact resistance and weathering properties can today be properly dealt with. However, all commodity polymers and virtually all high-performance materials are oil based. Currently, about 6% of the world oil production is used for the chemical product tree, among which monomers are only one

branch. If light crude oil were becoming increasingly scarce, a political and social decision would then be necessary on whether most of the produced oil simply be burned or rather transformed into value-added products.

Independently of when is raised and how it will be solved, the future will see a significantly increased focus on polymers from renewable resources having full biodegradability. Here, two aspects will be important: (i) substituting commodity polymers such as PE and PP by materials with appropriate properties and made from renewable resources that are available in sufficient quantities and (ii) finding substitutes for engineering polymers, in particular the polyamide and polyester families. An example that is already well on track is poly(lactic acid) (PLA), with a current annual production of approximately 150–200 kt, for instance, used for packaging. However, promising substitutes for important families such as polyamides have yet to come.

Hybrid Inorganic–Organic Polymers

Karl-Heinz Haas and Gerhard Schottner

Fraunhofer-Institut für Silicatforschung, Würzburg, Germany

1 Introduction

Nowadays, glasses and polymers are materials that have found widespread applications in nearly all aspects of our daily life. Very early on, scientists and engineers have also tried to design composite materials, such as fiber-reinforced polymers, which combine specific properties of glasses and organic polymers to fulfill requirements that could not be met by a single class of products. But these materials are macroscopically heterogeneous because the glass and polymer phases remain distinct. Further advances to achieve unique properties would require to integrate homogeneously, at the atomic level, two different phases, be they polymer, glass, ceramics, or metal, to form real *hybrid* materials in the same sense as hybrid animals or plants are crossbred from different species [1, 2].

The only means to produce such homogeneous materials from a priori incompatible elements of course rely on low-temperature chemical methods using molecular precursors. Various types of hybrid materials obtained in these ways have been described in the literature [3–10], for instance, interpenetrating inorganic and organic networks, organic dyes in inorganic matrices, core-shell organic–inorganic particles, and many others. In the present chapter, we will focus on the combination of inorganic glass-like structures and organic polymers called inorganic–organic polymers (IOP) as synthesized by the sol–gel process. These materials can uniquely combine the properties of glasses (e.g. high transparency, mechanical stability) and organic polymers (e.g. flexibility and workability at lower temperatures as compared with glass-melting processes).

Standard inorganic sol–gel processing (Chapter 8.2) was invented in the midst of twentieth century with the initial goal of preparing glasses and ceramics from liquid precursors [3]. During the late 1970s, this method has been extended to the incorporation of organic network modifiers into an inorganic oxidic network to form the so-called organically modified silicates (Ormocils). In a next step, not only could functionalization of the inorganic network be realized but also the possibility to synthesize additional organic crosslinks/networks between the inorganic units. As will be discussed here, this achievement was the beginning of IOP materials termed ORMOCER®. These are thermosetting materials, so that shaping processes are irreversible upon final curing – an important difference with respect to thermoplastic polymers or inorganic glasses whose shaping can be repeated several times if necessary. Since the variability of organic groups is quite high, a large playground for the synthetic chemist and material scientist opened up, leading to interesting applications in the field of coatings, bulk materials, fibers, and composites [5, 7, 8]. A small selection will be described in this contribution.

2 Sol–Gel for Hybrid Materials

2.1 Precursors, Chemistry, and Processing

Because the basic principles of sol–gel processing need not be described again (see Chapter 8.2), we will focus instead on special features relevant for IOPs. In contrast to pure inorganic sol–gel materials, IOPs have organic functionalities connected to the inorganic network and, often, also an organic crosslinking/network connected to the oxidic structures. Although not all of them are present in real IOP, possible structural units are summarized in Figure 1 to illustrate the basic principles at work.

Based on these structural elements, materials ranging from highly inorganic to pure organic in nature – as well as intermediate hybrids – can be synthesized.

To various degrees, the inorganic silica network can be modified by heterometal oxidic structures $M-O-Si$ ($M = Al, Ti, Zr, Sn$) as well by nonreactive organic groups (R). One organic group per Si-atom opens the inorganic network to a certain extent, sometimes creating porosity in the materials; if two organic groups are introduced at the same Si atom, the inorganic network is drastically modified, evolving toward linear networks of silicone-type structures.

The inorganic network can become connected through introduction of reactive organic groups, forming interpenetrating networks. If the organic connection is short, one obtains hard, elastic materials whereas more flexible ones are generated when the spacer length is long. The spacers can be further modified with functional groups that, for instance, yield special adhesion properties on various surfaces. If even more organic structures are connected to the hybrid network, the material becomes more akin to an inorganically modified organic polymer, which can be of practical interest when a bulk material with a high mechanical flexibility is required.

Actually there exists a complete spectrum between purely inorganic and organic polymer networks depending on which precursor is used among the four main

different types that have been defined (Figure 1). In practice, one can achieve highly interesting combinations of properties just by choosing the appropriate precursor that will generate the desired structural unit. Metal alkoxides ($Si-, Al-, Ti-...$) are, for instance, used when a purely inorganic network is to be built (type-I precursors) whereas modifications of an inorganic network are based on type-II precursors with hydrolytically stable $Si-C$ bonds (see Figure 2).

With type-III precursors, one forms organic crosslinks/networks between inorganic units by reaction of Si-bonded (meth)-acrylic or epoxy groups. Also mercapto-/vinylalkoxysilane reactions are often used, especially in UV-curable systems. They lead to short organic chain crosslinks between the inorganic units avoiding at the same time the use of UV-initiators.

If type-IV purely organic monomers are used (e.g. acrylates), copolymerization with the organic reactive groups of type-III precursors can occur, which extends the character of the IOP even more toward that of organic polymers. Some influences of the modification of the basic $Si-O-Si$ network on the properties of materials are shown in Figure 3.

Flexibility/elasticity is mainly determined by the amount of pure organic structural units or organic crosslinks with long spacer groups. The nonreactive functionalization is very often used to control the polarity

Figure 1 Structure of glasses, silicones, and organic polymers, which can be synthesized using specific precursors (type I–III shown in Figure 2) leading to hybrid inorganic–organic polymers.

Figure 2 Examples of different precursor types (I–III) for sol–gel/hybrid materials forming inorganic, organic networks, or for modifying the inorganic network; beside Si-alkoxides also other metal alkoxides can form inorganic networks.

Figure 3 Resulting properties of IOP by the modification of $\equiv\text{Si}-\text{O}-\text{Si}\equiv$ network by heterometal elements, organic monomers, nonreactive and reactive functionalization.

(hydrophilic/hydrophobic), to generate special functions like antistatic or antimicrobial properties, or even to synthesize porous materials when mainly inorganic sol–gel networks are formed. Substitution of Si in the network by other elements (i.e. Ti-, Zr-, Al-, Sn-, or others) can increase the hardness of the hybrid network and allow the refractive index to be controlled. The reactivity of these hetero-metal alkoxides in the hydrolysis step is quite high compared with that of other reacting organically modified Si-alkoxides. Hence, modification of metal alkoxides (chelates, complex formation, etc.) is necessary to slow down their reactivity and guarantee a homogeneous material at a molecular level.

The processes leading to IOP usually require two steps, the first being the hydrolysis and polycondensation

First step: formation of inorganic network

Hydrolysis

Polycondensation

(possible cocondensation with other metal alkoxides –Ti, Al, Zr...)

Second step: formation of organic network/crosslinking

Crosslinking of Si-bound monomers,
copolymerization with non-Si-bound organic monomers also possible

reactions as in the case of pure inorganic materials (Figure 4). This first step runs at low to medium temperatures in solution (i.e. below 100 °C) and results in organically modified $\equiv\text{Si}-\text{O}-\text{Si} \equiv$ clusters in a liquid dispersion, the sol. The hydrolysis and condensation reactions themselves are pH-sensitive, so that in many cases the pH has to be adjusted to acid or alkaline conditions. As described in Chapter 8.2, pure metal alkoxides are not miscible with water so that a common solvent – often alcohols – is used as a starting homogeneous solution. The resulting sol/resin can then be processed as in classical sol–gel processing to yield particles, coatings, fibers, or bulk materials. After the shaping step, one finally cures the materials to complete the inorganic network forming reactions and build the organic network/crosslinking (second step in the reaction) by heating of the samples at up to 200 °C, by UV irradiation or even by atmospheric plasma treatment in nitrogen [11].

Radical initiators are used for UV-curing whose advantages are to be very fast and energy efficient. In some cases, oxygen inhibition of the radical polymerization reaction has to be prevented through a nitrogen purge. Since vinyl-/mercaptopalkoxysilane reactive systems can often be used without UV-initiator, they are very favorable in biomedical applications or for coatings with possible food contact. Owing to mild curing conditions, the organic functionalities remain in the IOP in which they ensure its desired properties and, in addition, allow thermally sensitive substrates like some polymers or even paper to be coated.

The formation of monolithic bulk materials or thick films of IOP can often be achieved without having to deal with shrinking processes during gel drying (see Section 4). A comparison between inorganic and hybrid sol–gel processing is shown in Table 1.

Table 1 Comparison of inorganic and hybrid sol–gel processes/materials (common sol–gel properties excluded, see Chapter 8.2).

	Advantage	Disadvantages
Inorganic	• Low-cost precursors • Temperature stability • Porous materials are easily achievable	• Risk of cracking • Bulk materials not easily achievable • Thermal treatment for sintering or crystallization needed • Organic functions can be introduced only through post processing
Hybrid	• Organic groups offer great functionalities when covalently bonded to network (stability) • Controlled polarity of surfaces • Soft processing conditions (temperature, UV) • Fast UV processing possible • Bulk materials achievable without cracking	• Precursors more expensive • Temperature stability limited due to organic functions • Crystallization of inorganic compounds often not possible due to temperature restraints

2.2 Overview of IOP Properties

As described in Section 2.1, the resulting properties of IOPs are determined by the basic structural units, which belong either to inorganic glasses or organic polymers. A comparison with various material classes made in terms of an Ashby plot [12] for the density–Young’s modulus relationship show that – as far as mechanical stiffness is concerned – the IOPs discussed in this contribution are more akin to reinforced organic polymers than to typical glasses or ceramics (Figure 5).

Many physical properties of IOPs that can be tailored through a combination of basic structural units are summarized in Table 2. In view of the higher atomic weights of the inorganic components, the density of IOPs is slightly higher than that of usual organic polymers. The thermal stability is mainly limited by the nature of the organic groups in the hybrid network, which makes these properties similar to those of organic polymers. Their mechanical properties (stiffness) range from very soft up to very hard depending on the amount of inorganic and organic domains, and especially on the spacer length between the crosslinked inorganic clusters. Since IOPs are homogeneous materials on a molecular scale, high transparency and low optical losses make them very well suited for optical applications (e.g. optical waveguides, micro optical components, fiber optical coatings, and sensors).

The electrical properties are tuned by the functionalization of the organic network from pure insulators/dielectrics up to ion-conducting polymers. The

Table 2 Overview of properties of hybrid polymers.

Property	Typical range of values	Comments
Density	1.1–1.6 g/cm ³	Without fillers
Thermal expansion coefficient	50–200 ppm/K 18–70 ppm/K	Without filler With filler
Thermal stability	180–400 °C	Less than 5 wt % loss (TGA)
Stiffness	0.0013 GPa up to 18.6 GPa	High organic content High inorganic content
Refractive index (at optical wavelengths)	1.42–1.62	Without fillers
Optical losses (1310, 1550 nm) (633 nm)	≥0.3 dB/cm ≥0.06 dB/cm	Not fluorinated
Electrical resistance	10 ¹⁶ Ω cm 10 ⁸ Ω cm 10 ³ Ω cm	Passivation Antistatic Ion conductors (H ⁺ /Li ⁺)
Dielectric number	≥3.2 at 10 kHz	Coatings
Dielectric losses	≥4·10 ^{−3} at 10 MHz	Coatings
Dielectric strength	100–400 V/μm	Coatings
Permeability for oxygen	From less than 10 up to 130,000 cm ³ /m ² d bar	Ideal for barrier coatings or contact lens materials or nonporous membranes

Figure 5 Ashby plot for the Young’s modulus–density relationship of various material classes and comparisons with transparent hybrid inorganic–organic polymers.

influence of the inorganic and organic network density is especially prominent regarding the permeability to gases. Highly permeable IOPs have open flexible organic networks [13], whereas barrier coatings based on IOPs show high condensation degrees and network densities [14].

3 Coatings

3.1 Capillary Forces and Precursors

The production of glasses and other inorganic bulk materials via sol–gel processing is more or less limited by the capillary forces that act during drying and result in important shrinkage (Chapter 8.2). To overcome this significant obstacle, supercritical drying is applied in the manufacturing of ultralow density materials (aerogels), which function as high-performance insulating materials and, therefore, require larger dimensions ranging

from mm to cm), since the insulating efficiency depends on the volume. Despite their extraordinary properties, the market penetration still remains low because of the high cost of such manufacturing processes (Chapter 8.3).

In contrast, thin sol–gel-derived coatings – either inorganic or hybrid – offer a chance to improve the surface quality of many products without major rise of their cost. Capillary forces upon drying are then fairly limited, thanks to a low thickness in the nm to μm range, which reduces the risk of cracking. This is the reason why careful investigations are made worldwide to arrive at cost-effective manufacturing processes for high added-value coatings on goods requiring high surface quality and environmental stability.

The most important precursors used in sol–gel processes are silicon compounds, namely alkoxysilanes and organo(alkoxy)silanes, potentially combined with main group or transition metal alkoxides. Their hydrolysis and condensation reactions initiated during sol–gel processing are well known as they have been extensively studied by various research teams. As silanol groups are formed by hydrolytic reactions of alkoxysilanes and organo(alkoxy)silanes, the protection and functionalization of glasses also exhibiting silanol groups on their surfaces has been the focus of early studies concerning the application of sol–gel-based coatings.

3.2 Coatings on Glass Surfaces

The corrosion of historic glasses through the formation of gel layers due to ion-exchange processes is a well-known phenomenon studied in detail by researchers in the field of cultural heritage preservation [15]. Because of inadequate chemical compositions (Chapter 10.8), many historic glasses are more prone to leaching than modern glasses. To reduce the potential damage of environmental factors, such as moisture and atmospheric pollutants on those highly valuable artworks, special coatings have been developed and applied on several historical sites throughout Europe.

In the case study of the Herrgottskirche in Creglingen (Germany), a coating generated by cohydrolysis of tetra-ethoxysilane (TEOS), diphenyl-diethoxysilane (DPDEOS) and methyl-vinyl-diethoxysilane (MVDEOS) has been applied on the exterior side of a stained-glass window from the thirteenth century exhibiting severe glass corrosion (Figure 6). The coating was applied in a workshop after de-installation and careful cleaning of the glass piece in 1988 and reinstalled afterward. In 2010, the condition of the coating has been assessed while scaffolding was available to renovate the stone facade. The condition of the coated glass surface has been

documented and photographed and a very small sample of the coating material removed. After these 22 years of exposure to sunlight, rain, and atmospheric pollutants

Figure 7 Micro-Raman spectra of exposed coating material (top curve) and freshly prepared reference sample (bottom curve). Main band assignments: $\nu(\text{C}=\text{C})$: 1592 cm^{-1} , $\delta(\text{CH}_3)$: 1451 cm^{-1} (br), $B_1\nu_{17}(\text{aryl})$: 1158 cm^{-1} ; $A_1\nu_{14}(\text{aryl})$: 1027 cm^{-1} ; $A_1\nu_6(\text{aryl})$: 998 cm^{-1} ; $B_1\nu_{18}(\text{aryl})$: 617 cm^{-1} .

(as the church is located close to a road), it turned out that the coating still adhered very well to the glass and exhibited no delamination, cracking, or other degradation phenomena.

The small coating sample taken from the surface of the glass has been analyzed by Micro-Raman spectroscopy and compared with a freshly prepared reference sample. Both spectra are identical (Figure 7); therefore, the environmental stability of this ORMOCER[®]-coating material seems to be fairly high, at least on this timescale. The composition of the coating had been designed to ensure high light stability, water repellence, optical transparency, and reversibility as it can be removed by dissolution in organic solvents (e.g. ethyl acetoacetate) to meet the standards of cultural-heritage preservation.

Concurrently, similar types of protective or decorative coatings for crystal glasses have been designed through combination of 3-glycidoxypropyl-trimethoxysilane (GPTMS), aluminum alkoxides, and organic prepolymers (epoxy resins) through cohydrolysis and cocondensation. Dip-, spray-, or spin coating procedures followed by thermal curing around $100\text{--}200\text{ }^\circ\text{C}$ result in highly cross-linked hybrid materials exhibiting thicknesses in the lower micrometer range. High abrasion resistance, optimal adhesion, simple colorability by incorporation of either organic dyes or inorganic pigments, and high gloss are achieved through these simple manufacturing procedures. The integration of organic constituents has been decisive to achieve high chemical stability, especially for glassware frequently subjected to dishwashing at high pH-values [5].

Figure 8 Low-energy hybrid polymer coating on glass: liquid droplet on the rim of a glass container easily removed, leaving little chances to spoil the surroundings.

Owing to the intricate hybrid network structure of these IOPs, the potential for migration of ions or molecules through this network is very low so that a high chemical stability can be expected. For high-lead crystal glasses, the leaching of lead ions is largely suppressed and, therefore, the coatings may be used as barrier films on glass surfaces [5]. At the same time, leaching of the individual constituents of the coating is also minimal and allows to meet FDA regulations for uses as drinking glasses or food containers.

The surface modification of glasses is useful to prevent not only the migration of small chemical entities out of the bulk material, but also to repel chemicals from migrating to the glass surface and wetting it. One best achieves this feature by designing hydrophobic and oleophobic coatings, which contain long alkyl chains or perfluorinated alkyl chains connected to the silica/silicone backbone. The high efficiency of these coatings originates in the separation of the long alkyl chains from the more polar parts of the sol-gel-based network (silanol groups and polyether chains). The nonpolar chains then find themselves enriched at the surface of the cured coatings and lower their surface free energy, as also achieved with perfluorinated organic polymers (e.g. Teflon[®]). With these coatings, special types of commercial crystal glass vessels are treated on the top rim to avoid droplets from adhering to the glass and rolling down on its external side (see Figure 8). Only a very thin layer (well below $1\text{ }\mu\text{m}$) is needed to change completely the wettability of the glass so that several hundred thousand glass vessels can be coated with 1 l of the coating solution. The coating process is a simple manual treatment using a sponge-type material.

3.3 Coatings on Metals and Polymers, UV- and Plasma Curing Techniques

Very often IOP compositions that are used as glass coatings are also applicable on various metal surfaces like Cu, Al, or steel to generate dense layers for corrosion protection or also as low surface free energy (“easy-to-clean”) coatings mainly based on precursors that are cured thermally (III.2 in Table 1) and are combined with perfluorinated alkylalkoxysilanes. Such an example of IOP coating on copper metal is shown in Figure 9.

A second type of precursor generating hybrid networks is 3-methacryloxypropyl-trimethoxysilane (MPTMS), which after hydrolysis enables the formulation of UV-curable IOPs [5]. This compound requires the addition of photo initiators in substantial amounts to trigger the photopolymerization of the acrylic groups. But the cohydrolysis and cocondensation of precursors such as vinyl-trialkoxysilanes and thio-substituted alkoxysilanes leads to IOPs’ crosslinking under UV irradiation without any photo initiator. Both reaction schemes require curing times of only a few minutes. They have been used to formulate scratch- and abrasion-resistant coatings on plastics [16]. The synthesis of silanes equipped with several acrylic substituents per one silicon atom (see e.g. Figure 10) has been performed to realize ultrafast curable coatings for glass fibers used in telecommunication [17] as well as in sensing devices (Chapter 6.4). The copolymerization of selected monomers enables application-oriented tailoring of properties like hardness, flexibility, refractive index, transparency, adhesion, and curing speed. The resulting tunable resins are especially useful to replace organic coatings in optical glass-fiber manufacturing because of their superior adhesion and mechanical performance. More recently, protective coatings for fiber

Bragg grating sensors have become a commercially available product offered by FBGS company in Jena, Germany.

An interesting optical application of micro/nanostructured IOPs has been made possible by embossing techniques. The so-called “moth-eye” patterns can be created to realize antireflective surfaces both on plastics and glass [18]. The patterning process is based on a two-step coating and curing scheme applicable through physical drying of the IOP resin and UV-curing after or during the embossing process. The sub-micrometer structures exhibit dimensions (width and depth) in the range of several hundred nanometers and, therefore, are not visible. Embossing is made possible since the IOP-resin shows high plasticity before curing. In addition, wetting can also

Figure 10 Bifunctional precursors for inorganic–organic polymer designed for bulk materials and composites and their role in network formation/connection, including an example for dimethacrylic silane.

Figure 9 Corrosion protection through hybrid polymer on copper substrates: left side, uncoated; right side, coated.

be controlled by the microstructure depending on the hydrophobic or oleophobic nature of the IOP. In the former case, the wetting angle of water on polymer or window glass substrates, for instance, may increase from around 105° for unstructured to above 140° for microstructured surfaces. This is an example of the well-known *lotus-leaf* effect.

In usual sol–gel processing, the wet-chemically deposited coatings are either cured thermally or by UV irradiation. In the last decade, however, alternative techniques like plasma processes or electron-beam curing have allowed novel properties of the final coating to be obtained.

Plasma exposure of coatings or plasma depositions of aerosol particles with metal alkoxides or prehydrolyzed sols have, for instance, proven to be feasible on glass or plastic substrates [11]. As an example, such a coating on a silicon substrate based on epoxysilane deposited with an atmospheric plasma (nitrogen-purge) can be thinner than 200 nm (Figure 11), which is up to 10 times thinner than achieved with usual wet-chemical coating and curing methods. An interesting point is that these coatings additionally show excellent adhesion to various surfaces – also resulting from the plasma pretreatment – and form very dense networks. These features are of course important in barrier applications or for corrosion protection. Since plasma treatment/curing processes lend themselves to continuous operations, they make some

Figure 11 Scanning electron micrograph of a plasma-deposited inorganic–organic polymer coating (epoxysilane-based, left side) on silicon substrate (right side), [11] with kind permission of VITO NV (Belgium).

IOP compositions also relevant to roll-to-roll techniques (R2R) whereby a flexible material on a roll is re-reeled after coating, a process that is becoming more and more important in sol–gel technology.

4 Particles

Other interesting applications of IOPs are (nano)-particles. Various morphologies and synthetic strategies are used in this field as recently reviewed [19]. One strategy is the attachment of ex-situ preformed components (e.g. nanoparticles to polymers, synthesis of polymers around nanoparticles). Others are the in-situ production of inorganic components in the presence of polymers, or a complete in-situ strategy where both components are reacted to form hybrid polymer systems. The hybrids described in this chapter are mainly of the in-situ type.

During classical sol–gel processing of hybrid polymers, the intermediate sol-state is based on hybrid clusters in a liquid medium. If the solvents are removed and the organic reactions have started, hybrid polymers particles can form, for example, via spray drying.

An interesting kind of hybrid polymer particles are the capsules, for example, used for controlled release systems. In this case, a hybrid polymer resin, mainly based on precursors of the type shown in Figure 10, is forced through a nozzle by a gas stream followed by UV-curing of the resulting hollow capsule. The chemical nature of the capsule material – from more inorganic to more organic (open networks, high flexibility, high gas permeation) – can be chosen in a wide area and different applications can be followed using this strategy [20]. Beside solids, even solutions with high amounts of water can be encapsulated, which is usually not easy to achieve.

5 Bulk Materials, Fibers, and Composites

As mentioned, shrinkage upon curing is often minimized by the flexible organic parts of the IOP network. Therefore, compared with purely inorganic sol–gel materials, IOP bulk materials and composites can be more easily processed. Special precursors such as biacrylate-silanes have been developed (Figure 10). They are used to ensure the possibility of adjusting both the organic network density and the spacer length between the inorganic and organic part of the IOP network.

These precursors are processed like others bifunctional silanes. In contrast to coating applications, however, for producing bulk materials, the IOP oligomers contain little or no solvent so that they can be used as resin (i.e. as 100%

solid systems). After shaping, the oligomers are finally cured either thermally, by UV, or even visible light. The shrinkage upon curing is lower than 10 vol %. This figure is much smaller than for usual organic monomers since the first inorganic polycondensation step has already taken place in solution, so that oligomers react instead of monomers in the final curing step. Besides, no monomers remain in the cured material, which is important for biomedical applications.

Especially based on these favorable properties, composites with IOP matrices have been successfully used in dentistry for more than 15 years, the IOP being cured by visible light after application of the flowable material into the tooth cavity [7, 8]. In dental fillings, the shrinkage is further reduced to only 1.2 vol % by the incorporation of high fractions of inorganic (nano)particle fillers [21]. Such a low value is especially important in dentistry because the presence of voids between the filling and the tooth provides much room for reaction sites where bacteria cause caries.

The possibility of UV curing for the IOP resins is also used to generate hollow fiber membranes with controllable permeability for oxygen and selectivity for various gases [13]. The thermal treatment of the dense hybrid material can result in nanoporous silica membranes with selective gas permeation rates [13].

Compared with classical polymers like PMMA, IOPs combine a high transparency with improved mechanical properties that makes them also useful for micro optical components such as waveguides [7]. These structures can, for instance, be formed with embossing techniques, UV lithography, or even two-photon induced polymerization (2PP). The last technique is an innovative one to

generate micro- to nanosized complex structures that can be applied in optics, microfluidics, and biomedicine [22]. Organic polymerization with 2PP techniques is initiated by an intense femtosecond-laser beam. The hybrid resin is transparent at this wavelength and also at the two-photon-wavelength. In the focal area, a photo initiator adapted to this 2P wavelength triggers the organic-polymerization reaction upon laser irradiation. With a computer-controlled system, the laser beam can be guided to develop micro- and nanostructures down to below 100 nm once solvents have removed the non-polymerized parts as in conventional lithography. Here, IOP resins demonstrate their superiority over purely organic monomers because little polymerization develops outside the laser beam through motion of low molecular-weight oligomers, which ensures very fine and smooth surfaces (Figure 12).

6 Perspectives

The field of hybrid inorganic–organic polymers has grown tremendously since the early 2000s in terms of both fundamental research efforts and product development [9, 11].

This contribution cannot cover all future perspectives, but some aspects might be mentioned. Single-source precursors [23] are developed, which widen the scope of hybrid materials. Polymerization techniques like living-radical polymerization generate very special morphologies including hierarchical structures [24].

Additive manufacturing (AM) methods will increase in importance in the near future, because of the potential

Figure 12 Scanning electron microphotograph of an inorganic–organic polymer structure generated by two-photon-polymerization (stl-File: <http://www.georgehart.com/rp/rp.html>).

they offer regarding special morphologies and individual forms with the possibility to produce individualized products [25]. The 2PP process is one example for an AM method whereas 3-D printing techniques using IOP resins in connection with conventional single-photon absorption by UV light will also be of interest in the coming years.

Biodegradable/-resorbable materials are also highly relevant not only because of environmental issues (stricter environmental regulations) but also for many biomedical applications like implants, tissue engineering, and the like (cf. Chapter 8.4). Here, the incorporation of biodegradable components or even active biomolecules into IOP structures will have much influence on the development of new biomaterials (Chapter 8.4).

Finally, since environmental concerns are becoming an integral aspect of material design and engineering, the question of life-cycle-analysis is also becoming important. Hence, the so-called *green chemistry* approach should and will be applied to existing and newly developed IOPs [2]. In other words, the outstanding features provided by hybrids will certainly lead to new interesting applications in the future and will offer a creative playground for material scientists and chemists alike.

Acknowledgments

This article is dedicated to our colleagues at Fraunhofer ISC, who were involved in the development of IOP in the last three decades.

Section IX. Environmental and Other Issues

Figure 1 Domestic waste transformed into a piece of abstract glass art: optical micrograph under polarized light of bottom ash from a municipal solid waste incineration plant (Arnoldstein, Austria). Dark glass fraction of about 60% along with skeletal melilite $[(\text{Ca},\text{Na})_2(\text{Mg},\text{Fe},\text{Al})(\text{Al},\text{Si})\text{O}_7]$, plagioclase $[(\text{Na},\text{Ca})(\text{Si},\text{Al})_4\text{O}_8]$, and opaque spinel $[(\text{Mg},\text{Fe},\text{Mn}\dots)(\text{Al},\text{Fe},\text{Cr}\dots)\text{O}_4]$ crystals. Sample width: 3 mm. *Source:* Photo: Soraya Heuss-Aßbichler.

That glass is ubiquitous in the modern world is made most evident by the facades of modern buildings whose glazing controls light and heat interactions with the environment (Chapter 6.8). What is probably less obvious are the technical problems that glass is raising by its brittle nature when used as a structural element in architecture. The various solutions reviewed by F. Bos and C. Louter rely on the use of panels of more resistant laminated or tempered glass, which are connected either mechanically or with adhesives in such ways as to limit the accumulation of stress at places where surface flaws would ultimately result in breakage (Chapter 9.1). Similar problems are faced in the glazing of cars and transportation vehicles in general. As described by R. Gy, laminated and tempered glasses are again used – in proportions that have markedly increased with the complex shapes made possible by modern forming processes – whereas new functionalities are being added to the glass surface in terms of vision, safety, heat, and noise control and even of information display (Chapter 9.2).

In the form of fibers, glass is the prime material for thermal insulation, thanks to its incombustible nature, recyclability, relatively low cost, and to the possibility of engineering its properties for specific uses: whereas *glass wool* optimizes the thermal resistance in terms of thickness, *rock wool* is a unique fire-proof material. Both kinds of fibers are hyperquenched glasses (Chapter 3.8) whose fabrication, properties, and advantages are reviewed by Y. Yue and M. Solvang (Chapter 9.3). Transparency and other traditional properties are also making glass an indispensable active or passive component of all forms of renewable-energy systems described by J. Deubener and G. Hensch, for example, as covers, substrates, or supports for photocatalytic devices (Chapter 9.4). In addition, glass is poised to become a key component in the new generation of all solid-state batteries whose safety will be much increased by the elimination of the current organic liquid electrolytes. Lithium and sodium sulfide glasses are the best potential materials to replace them for the reasons discussed by A. Hayashi and M. Tatsumisago, namely low processability temperatures, high electrical conductivities, wide electrochemical windows, appropriate elastic moduli, and excellent cycle performance (Chapter 9.5).

Closely related to the energy problem is the tremendous growth in glass production in Asia – especially China – during the last few decades, which should also take place in other countries that are developing rapidly. Following a long century of incremental improvements in the production of flat glass, the float-glass revolution of the 1960s not only made this expansion possible but has since then resulted in a continuous decrease in selling costs as explained by B. Savaète (Chapter 9.6).

In spite of rising energy prices, more efficient glass melting furnaces have been one of the factors that have

driven production costs down. Although furnaces belong to only five main types, depending on the energy source, heating systems, and energy recovery via either regenerators or recuperators, C. Jatzwauk explains why each of them must be tailored to specific factors that include the type of production, the intended pull, and the local labor and construction costs (Chapter 9.7). By considering furnaces as chemical reactors and heat exchangers, R. Conradt and E. Muijsenberg then deal with their energy efficiency and describe how this parameter is evaluated and optimized with methods that include finite-element modeling of their design and operation (Chapter 9.8). As already understood and practiced in Antiquity, glass is a material that can be indefinitely recycled. Although it lends itself particularly well to the concept of circular economy and to savings in both energy and raw materials, the practical problems faced by cullet recycling are summarized by S. Ceola and N. Favaro with regard to glass collection, elimination of undesirable impurities, and regular delivery of a material of a quality suitable to the demanding modern glassmaking processes (Chapter 9.9).

The next two chapters deal with glass as a waste-storage matrix. For domestic and industrial waste, aluminosilicate glasses (Figure 1) are major by-products of incineration processes whose main goals are to reduce the volume of the waste to be disposed of in landfills, to eliminate toxic and biological agents, and, possibly, to recover energy. As discussed by S. Heuss-Aßbichler and A.P. Bayuneso in their review of incineration processes, the glasses produced should themselves be stable if disposed of in landfills or as road-base materials, or better, be usable as starting products in the fabrication of cement or ceramic materials (Chapter 9.10).

For radioactive waste, glass is a matrix that, in contrast, has been highly engineered to incorporate in a stable material the elements to be disposed of permanently. Among the matrices discussed by O. Pinet et al. in their worldwide review of vitrification processes and facilities, borosilicates are generally preferred for this application because of the large amounts of foreign elements they can dissolve, their long-term stability ensured by a good resistance to aqueous corrosion, and their low processing temperatures, which make robot-controlled production under highly radioactive conditions less difficult (Chapter 9.11).

To conclude this section, the chapter devoted by J.M. Parker to the International Commission on Glass (ICG) draws attention on the important role that this body has played since its creation in 1933 as a forum for discussing the most pressing technical, scientific, economic, and environmental issues within the glass community at large through its technical committees (24 as of today) and the recognition given by its awards to distinguished glass scientists and technologists (Chapter 9.12).

Structural Glass in Architecture

Freek Bos¹ and Christian Louter²

¹ Unit Structural Design, Department of the Built Environment, Eindhoven University of Technology (TU/e), Eindhoven, The Netherlands

² Institute of Building Construction, Faculty of Civil Engineering, Technische Universität Dresden (TU Dresden), Dresden, Germany

1 Introduction

The diversity of glass applications in construction designated as *Structural Glass* is illustrated by point-fitted glass, glass floors and stairs (Figure 1), or balustrades and façade fins (Figure 2). Glass (roof) beams are becoming more common (Figure 3) whereas glass walls carrying vertical loads or providing lateral stability can be found in a number of projects. Full glass structures with columns, beams, and stability walls all in glass are still rather exotic (Figure 4). In the terminology, it is easy to confuse “Structural Glass” with “Structural Glazing.” The latter, however, specifically refers to glass panels that rely on structural silicone adhesives to connect them to the supporting structure, rather than mechanical fixings. The former has the much broader meaning indicated above.

The history of structural glass is still very young. Although the glass panels used in the conservatories of the nineteenth century often provided stability to the cast-iron structural frames, the current developments can be traced back only to the 1970s. In England, the Willis Faber Dumas building in Ipswich and the Sainsbury Art Centre (Figure 5) in Norwich, both designed by Norman Foster, featured glass fins perpendicular to the glass façade to carry wind loads back to the main structure. The underground extension of the Louvre Museum in Paris featured an early application of glass beams. At the Cité des Sciences et de l’Industrie in the Parc de la Villette in Paris, a façade in which glass panels hanging directly from each other was first constructed (Figure 6). Subsequent milestones included glass half-

portals, a glass footbridge in Rotterdam (Figure 7), a cantilevering glass canopy in Tokyo, several glass staircases, and a free-standing full glass pavilion in Riyadh.

Around the turn of the last century, the development of structural glass gained momentum and the number of projects in which it was used increased exponentially. The extensive use of structural glass by the Apple company in its flagship stores has been an important driving force. The number of research projects at universities focusing on structural glass applications increased accordingly. In spite of growing coverage by codes, education, and research activities, however, it is still a field requiring specific expertise and therefore covered by a relatively limited number of specialist professionals.

This chapter provides an introduction on the issues related to structural design of glass. For further in-depth reading, [2–4] are recommended. Also notable is [5], which provides a thorough introduction into the field, including considerable attention to building physics. In preamble, however, note that structural glass is often part of the building envelope. Considerations of energy performance (most notably thermal insulation and light) are, therefore, often as important as the structural aspects. However, these are beyond the scope of the present chapter.

2 Scheme Design

For a significant part, the schematic structural design of a glass structure is governed, directly or indirectly, by the brittleness of the material (Chapter 3.11). This peculiarity sets it aside from the design of structures made up with other materials such as steel or reinforced concrete and requires specific attention, particularly at the points

where stress is exerted on glass pieces. As an example, drilling in the glass causes local damage/defects at the perimeter of the hole, which may significantly lower the local strength. Grinding and polishing of the hole perimeter to remove or at least reduce the defects is, therefore, recommended whenever possible.

Brittleness has a number of unfavorable effects on the structural properties of glass [6]. Under increased loading, glass elastically deforms linearly up to failure without providing any warning signal that breakage is imminent. Because peak stresses cannot be redistributed, the strength of an individual piece under a certain loading highly depends on microscopic surface defects, known as Griffith flaws, as well as on possibly present macroscopic accidental flaws (Chapter 3.11).

As a result, the theoretical failure stress of glass, based on the relation between Young's modulus, fracture surface energy, and atom equilibrium spacing [7], is around $32 \cdot 10^3$ MPa, whereas the characteristic bending tensile

Figure 7 Glass foot bridge, Rotterdam, The Netherlands; Kraaijvanger Urbis, ABT/Rob Nijssse [1]. Source: Photo C. Louter.

strength of float glass obtained from practical experience and experimental testing is only 45 MPa. The flaw-governed nature of the failure process also results in a very high scatter in strength test data and in difficulties in predicting the failure load of an individual piece of glass. This is illustrated by test data on glass beams plotted in a Weibull diagram (Figure 8).

Furthermore, since glass has a very low fracture surface energy of $2\text{--}4 \text{ J/m}^2$, it takes little energy for a crack to propagate through the material. As a result, fractures tend to run through a piece of glass completely, and not to remain localized. In addition, Griffith flaws show subcritical crack growth under the influence of tensile stress and humidity (known as static fatigue or stress corrosion), which causes the strength of glass to reduce over time (Chapter 3.11). This feature, too, makes predictions of the strength of an individual element difficult. Combined with the lack of a warning signal before failure and often complete breakage, this calls for specific measures in structural glass design. These concern the following points in particular:

- **Safety:** owing to its material properties, glass is of itself unsafe as a structural material. It lacks robustness and produces very sharp shards that can easily cause injury. Nevertheless, several strategies can be applied to obtain sufficient levels of safety. In the schematic structural glass design, these strategies need to be determined, as further discussed in Section 4.1 of this chapter.
- **Strength:** a range of models have been proposed to describe the strength of glass [10]. In practice, modern

Figure 8 Weibull plot (see Chapter 3.11) for glass panels tested either standing (in-plane loading) or lying (out-of-plane loading) [8, 9].

codes take into account the uncertainty in individual glass pieces through partial safety factors and a number of other parameters, as discussed in Section 4.2. The statistics regarding, for instance, the appropriate frequency distribution behind these factors, however, are still very much debated [8, 11]. So is, therefore, the truly obtained level of reliability.

- **Static scheme:** because of the susceptibility of glass to peak stresses, the distribution of these stresses should be predictable. This condition generally means avoiding unnecessary constraints and statically indeterminate structures. If this cannot be avoided, the actual resulting stresses should be checked thoroughly.
- **Material:** glass-only structures are rare. Glass is usually combined with steel, although glass-timber structures also exist.
- **Sizing:** practically all glass used in buildings is soda-lime silicate produced through the float process, often simply referred to as float glass (Chapter 1.4). Thus, the material is only available as flat sheets with typically a maximum size of 6×3.21 m, although sheets with lengths of up to 18 m have become available. For schematic design, choices have to be made on how the structure will be segmented because it is actually impossible to weld or cast soda-lime silicate glass, contrary to other materials such as steel or concrete. Also note that a limited number of thicknesses are available for glass sheets. The standard values are 3–4–5–6–8–10–12–15–19–25 mm, the last three being increasingly expensive. Theoretically, it is possible to laminate a large number of glass layers together, but only double laminate is a standard product and accordingly priced.
- **Connections:** the type of connections needs to be selected on the basis of the size of the glass element

and the structural system. Options are further discussed in Section 5.

- **Possibilities for replacement:** glass can be damaged easily without any established repair agents such as mortars. As the damages are often also very visible, the very practical possibility to replace an element should not be overlooked in structural glass design. The importance of this constraint increases with the size of an element and its role in the structure. Besides, new pieces of special glass elements may not be available after a project is finished, or they may be very expensive or take a long time to be produced again.

3 Float-Glass Processing for Structural Applications

In structural glass engineering, two methods of glass processing are of vital importance: laminating and strengthening.

3.1 Laminating

Laminating is the bonding of two or more sheets of glass together by means of polymer interlayers (Chapter 9.2). Laminated glass has the significant advantage that breakage of one glass layer does not necessarily result in failure of the whole panel, as the other layer(s) may maintain the functionality. It is therefore the primary method to create redundancy and safety in structural glass.

By far the most common laminate material is polyvinyl-butyl (PVB) foil. This product was invented in 1903 and found an application in the windshields of cars in the 1930s. Commonly, one produces PVB-laminated glass

by layering the glass and PVB in an autoclave where, under increased pressure and temperature, the PVB melts and adheres to the glass. Vacuum bags are also used sometimes, particularly with complex shapes or individual (prototype) specimens. Other interlayer materials include ethylene vinyl acetate (EVA), which is used most in solar panels, modified PVBs (acoustic), and thermoplastic polyurethanes (TPU).

The so-called ionomer laminate foils (under the trade name of SentryGlas®) have been applied approximately since the beginning of the twenty-first century [12]. They have a much higher strength, stiffness, and tear resistance than regular PVB. Originally, this interlayer was developed to create glazing resistant to airborne debris in hurricanes. But it has also significant advantages from a structural engineering point of view. Within a larger range of temperatures, it allows the section to work more as a monolith, rather than as a layered structure. This property greatly increases the stiffness of a panel and results in a significant residual strength even if all glass sheets in a laminate are broken, something that one cannot achieve with softer foils such as traditional PVB. Other stiff interlayer foils are also being applied nowadays, such as the Saflex DG Structural Interlayer, a PVB with an adapted formulation.

Apart from foil interlayers, resin-based interlayers can be applied. These are poured in a thin cavity between glass sheets in a liquid state and then cured. During curing, the interlayer adheres to the glass. Because of their

low tear resistance, resin-based interlayers are seldom used nowadays.

3.2 Thermal Prestressing

Whereas laminating is primarily done to increase safety, strengthening is applied to increase long- and short-term resistance to tensile (peak) stresses (Chapter 3.12). Usually, strengthening is achieved by thermal prestressing, which involves heating evenly the glass sheet to a temperature of around 720 °C, and quenching it by blowing cold air over the surfaces (Figure 9). This causes the outer surface of the glass to solidify without shrinking. The inner core, which cools at a slower rate, shrinks during solidification, thus creating compression in the outer surface, and tension in the core. With thermal prestressing, the stress profile is parabolical through the thickness (Figure 10).

As glass fracture always starts from peak tensile stresses around defects in the glass surface area, putting the surface into compression results in a higher load-bearing capacity of the glass sheet: the surface compression thus has to be overcome before tensile peak stresses can develop. Another major advantage of the surface compression layer is that it provides significant protection from stress corrosion, as the surface only comes into tension under extreme loading conditions. In thermal prestressing, a distinction is made between heat strengthened and thermally tempered (or toughened) glass.

Figure 9 Schematic representation of the thermal tempering process [13].

Figure 10 Through the thickness stress profiles of strengthened glass, from left to right: fully tempered (or toughened), heat strengthened, and chemically strengthened [6].

Figure 11 Fracture pattern of (a) annealed, (b) heat-strengthened, and (c) fully tempered glass [2].

The load-bearing capacity of thermally prestressed glass is usually defined as the sum of the surface compression stress introduced by the thermal process and the short-term bending tensile strength of annealed float glass ($\sigma_t = 45$ MPa for a 95% fractile; the surface compression is considered 0 MPa, although in reality this is usually several MPa). European codes such as NEN 2608:2014 [14] require $\sigma_{t,95\%} \geq 120$ MPa for tempered glass and $\sigma_{t,95\%} \geq 70$ MPa, which implies minimum surface compressions of 75 and 25 MPa, respectively. Research [8] has shown that this simple summation approach is not completely valid to describe the load-bearing capacity of thermally prestressed glass, but that it remains a sufficiently accurate approximation in structural glass engineering practice.

Besides the surface-compression level, the major difference between tempered and strengthened glass is the fracture pattern (Chapter 3.12). The former breaks into very small dice-like fragments, whereas the latter has a fracture pattern more similar to that of annealed glass, i.e. yielding relatively large shards (Figure 11). This is considered an advantage in structural applications of laminated glass panels, as it allows a degree of residual strength and stiffness in a heat-strengthened laminate after breakage. In contrast, a thermally tempered laminate will act as a wet blanket after breakage of all layers. This may result in collapse of the panel, for instance, by tearing and/or slipping from its (point) supports. The combination of increased strength, stress corrosion resistance, and favorable fracture pattern has thus led heat-strengthened glass to become the preferred material in structural glass engineering.

Although major prestresses are created in this way in the glass surface, it is important to realize that they are not evenly distributed throughout the whole sheet. As a result of boundary effects, the cooling differential between the inner sheet and the outside is smaller at the corners, along the edges and around holes. The level

of prestress that can be achieved is therefore lower in these areas. Structural glass codes provide instructions on the size of these areas (generally about 1–1.5 times the thickness) and the prestress reduction that should be taken into account, which can be up to 100% at the corners according to codes such as the NEN 2608:2014 [14]. If the highest stresses occur in these areas, the application of thermally prestressed glass may not be as advantageous as one would think from the general level of prestress that can be obtained.

As described in Chapter 3.12, a problem found for thermal prestressing, particularly tempering, is the failure caused by the presence of nickel-sulfide inclusions in the glass, which can take up to 10 years to manifest itself on north-oriented façades.

3.3 Coating

Often, coatings are applied to one or both surfaces of a glass sheet (Chapters 6.7 and 8.2). Metallic coatings, for instance, reflect sunlight selectively with regard to wavelength, i.e. they can be adjusted to reflect certain parts of the daylight spectrum (Chapter 6.8). As the 390–750 nm visible spectrum represents a small part of solar electromagnetic radiation, significant reductions of transmitted solar energy (g -value) can be obtained without grossly compromising the transparency. For instance, neutral solar reflective glazing can transmit around 70% of the visible light (untreated glass: around 80–85%), with a g -value of only 40% (in commercial products, these numbers are often added to the product name, in this case as 70/40). Therefore, the application of metallic coatings to façade and roof glazing has now become commonplace.

Organic coatings are also applied increasingly. Often dubbed “self-cleaning,” they make it difficult for particles to adhere to the glass surface, resulting in decreased need for cleaning, although they do depend on rain to let the panel actually be cleaned.

Metallic and organic coatings are too thin to have any structural function. There has been research into the possible effects of stress corrosion reduction and protection from surface damage [10, 15], but this direction has not been pursued extensively and has not led to generally accepted or understood results.

3.4 Mechanical Processing

In spite of the troublesome brittleness of glass, several ways of mechanical processing have been developed. Cutting is the most common method to obtain a glass sheet of the required size. This involves scoring the glass with a cutting wheel on one side and subsequently breaking it. Straight cutting can be done either manually or with a machine if not on site, but training is required to make clean cuts through glasses thicker than 12 mm for which obtaining a clean break is more difficult. Some machines are capable of cutting two-layer laminates by scratching each of the glass sheets on the opposite surface. Cutting in curves is also possible. Other methods are machine-disc sawing, water-jet, and laser-jet cutting, but they are more time consuming. These techniques can be applied to obtain glass panels of any shape.

After cutting a panel to size, the edges are often beveled, ground, and sometimes polished to obtain smooth edges, safe to touch, and with smaller edge defects. This is particularly important when the edges are in sight (and can be touched), or when significant edge stresses are expected, for instance, because of differential thermal expansion loads.

Techniques have been developed to drill holes in glass sheets with purpose-made diamond-covered drills. These are used for point-fixed glazing. If the glass is to be prestressed, the holes should be drilled before the thermal treatment. This requirement may cause alignment problems if the panel is then also to be laminated. Drilling can only be done under controlled conditions in a shop, otherwise it is very likely that it will either cause immediate breakage or result in large surface flaws that may cause premature failure later. Unless for diameters of at least 40 mm, it is not possible to polish the inside of a drilled hole. A reduced strength should therefore be accounted for when the edge of a drilled hole is loaded.

4 Design and Detailing

4.1 Safety Approaches

Owing to the failure behavior of the material, the safety of a glass structure requires specific attention [6]. The basic assumption should be that all the glass in the structure can break. The extent to which this precaution is taken

into account depends on the risk profile of the application (i.e. a broken window pane is less of a problem than a broken glass floor element). In their most elaborate form, quantified requirements are set for:

- The resistance, particularly against specific actions such as drop and sway impact with hard and/or soft bodies.
- Residual resistance for a specified period of time, making distinction between residual resistance at increasing levels of damage (one, more, or all glass layers broken).

Modern structural glass codes apply this approach.

To determine the risk profile, qualitative or quantitative scenario approaches can be applied in which the possible causes of damage are systematically reviewed. The extent of such an analysis depends on the particularity of the application. Typical scenarios can include collision with road vehicles, cleaning machines, vandalism, bomb-blasts, etc. A scenario approach should include consideration of the possible loading after the incident and the time required to take protective measures and to make replacements.

There are basically two strategies to avoid detrimental effects of glass failure, which are often combined: reducing (i) its probability and (ii) its consequences.

An important way to reduce the probability of failure is to maintain high-quality standards throughout the design and construction process, including thorough design review, specialist training of handlers and construction workers, production quality control (e.g. heat-soaking for thermally treated glass, which speeds up the α - β -transition of nickel sulfide inclusions), and even well-specified transport and storage conditions. Also, it is important to avoid excessive time and financial pressure, as glass failure is more often than not caused by errors in the design, production, handling, transport, or construction. As damage is often caused by incidental impact, applying protective measures such as edge covering or physical anti-collision elements can also significantly reduce failure probability.

Because reducing the probability of breakage is not enough to obtain an acceptable level of risk, measures also have to be taken to reduce the consequences of a failure. As it is impossible to improve sufficiently the material properties themselves, glass is usually laminated (see Section 3.2). This results in transparent composite elements with significantly higher resilience. Generally, as long as at least one glass layer remains unbroken, such an element will possess significant residual strength. Experimental research has shown that laminating provides an effective barrier to macroscale crack growth through structural elements. Depending on the layout, interlayer material, and level of prestress (i.e. tempered,

Figure 12 Principle of the alternative load-path design in the hanging glass façades of Cité des Sciences at La Villette in Paris: the panels are joined with cross-shaped connectors, allowing a redistribution of loads through adjacent panels in case one should break [6].

heat strengthened, or annealed), the element may still possess significant residual strength even if all glass layers are broken. If very high safety standards are required, steel profiles may be added to such a glass laminate to obtain very high residual strengths (see Section 6.5). If applied to glass beams, this often results in strain hardening behavior, and thus to failure behavior comparable to that of reinforced concrete [13].

In addition to reducing the consequences of failure of the structural *elements* themselves, it is possible to apply measures in the overall *layout of the structure*, in the form of alternative load paths. Such a scheme is shown in Figure 12 for a façade of glass panels hanging one from

another. The cross-shaped connection elements allow the loads of a panel beneath another one incidentally broken to be carried by the adjacent rows of panels. Another example (Figure 13) is that of a catenary reaction that will be activated perpendicular to the main load-bearing direction in case a glass beam would fail. Generally, the maximum load and stiffness of such an alternative load path is significantly lower than that of the primary load path.

4.2 Structural Analysis

At first sight, calculations of the structural behavior of glass are rather simple since a linear elastic response is assumed up to failure. Generally, a Young's modulus of 70 GPa is retained, although measurements have shown that actual Young's moduli may vary roughly between 65 and 75 GPa.

Nevertheless, some particularities should be considered:

- Because of the susceptibility to micro- and macrosized surface defects, the strength of individual glass sheets shows a large scatter. In structural analysis, one usually accounts for it by applying significant material partial safety factors (e.g. $\gamma_M = 1.8$ for analysis with wind loading, 2.0 for other loads according to NEN 2608:2014 [14]).

Figure 13 (a) Wolfson Building glass roof, Glasgow, UK, (b) schematic section of the glass roof, in undamaged condition, (c) schematic section after fracture of one of the glass beams. If, for whatever reason, one beam fails, loads can be redistributed to the adjacent beams through catenary action (perpendicular to the beam length axis) in the roof panels [6].

- The strength depends on the humidity and tensile stress history (which induces subcritical crack growth). In strength analysis, this variability is usually covered by a factor k_{mod} , which ranges approximately from 0.3 for permanent loads to 1.0 for (five seconds) wind loads. In structural calculations, different checks should be made for each governing action with different durations.
- The edges of a glass sheet possibly have larger surface defects than the front and back faces. The location where a stress acts should therefore be considered and, in most cases, specifically checked since failure can take place at a lower strength if the stress is applied to the edge compared to a face.
- In heat-treated glass, the strength results from differential cooling rates and, therefore, depends even more on location than in annealed glass. Along edges and bore-holes, the effect of heat treatment is reduced. At the corners it should even be considered nonexistent. Different checks may be required, depending on the stress distribution.

For glass, another difficulty is that one cannot rely on any a priori form of stress redistribution. Therefore, unless the structural design presents a clear-cut analytical solution, finite element modeling is often applied to locate and quantify local peak stresses. Geometrically nonlinear analysis is usually called for, as elements tend to be slender (great length and width compared to thickness), resulting in nonlinear deflection behavior in out-of-plane loading (e.g. façade panels) and stability problems in in-plane loading (e.g. beams).

Because glass plates are often assembled into laminates for safety reasons, their structural properties are also determined by the mechanical properties of the interlayer material. As these are always polymers, their behavior depends on a number of parameters of which load duration and temperature are the most important. Together with the material composition, they determine the effective stiffness and, thus, the extent of coupled action of the glass sheets in a laminate. Specialist software exists in which the most relevant interlayer properties, load durations, and temperatures have been incorporated.

5 Connections

5.1 General Considerations

Over the years, several kinds of connections for (structural) glass members have been developed. In the present chapter, a distinction is made between mechanical and adhesive connections. The former typically involve metal parts such as steel plates and bolts that either clamp around the glass or penetrate through it, whereas

adhesive connections generally involve (metal) parts bonded to the glass surface. Mechanical connections are most traditional and most commonly applied, the more so because adhesive connections – apart from structural sealant glazing (see Section 5.3.1) – currently suffer from uncertainties in durability and long-term behavior.

In view of the variety of designs, it is not possible here to cover them all in detail. Rather, we will focus on typical examples of both kinds. However, a few key points should be mentioned first.

Connection forces can be transferred at the surface, at the edge, or at a bore-hole edge of a glass member. At the surface, the forces are commonly transferred via contact pressure, friction, or shear interaction (e.g. adhesive bond), whereas contact pressure is involved at the edge (e.g. setting blocks) or borehole edge (e.g. bolted connections). Besides, all machining (e.g. cutting, grinding, polishing, drilling, or laminating) should generally be done before the glass members are assembled because, as already stated, the material cannot easily be tailored on-site. This complication affects the connection design and implies that careful consideration of tolerances should be taken. In addition, it is essential to avoid direct contact between glass and “hard” materials such as steel, concrete, stone, etc., which may cause high local stress concentrations and cause fracture of the glass. To avoid direct contact, “soft” intermediary materials such as neoprene, pure aluminum, nylon, or EPDM are often used. Finally, hinged connections are generally preferred, as they limit force concentration compared to rotationally rigid connections.

5.2 Mechanical Connections

5.2.1 Mechanical Point-Fittings for Façade Glazing

Mechanical point-fittings are often applied to connect glass panels to one another and/or to the supporting substructure (Figure 14). These connections are generally applied for glazing in façades. A schematic overview of typical point-fittings is provided in Figure 15.

Clamped point-fittings, as shown in Figure 15a, basically consist of small (metal) plates that clamp the glass panel back to the supporting substructure. Often EPDM gaskets are applied to avoid direct contact between the metal clamping plates and the glass. The clamped point-fittings are typically positioned at the perimeter of the glass panel and carry the out-of-plane loads that act on it. The in-plane loads are normally carried separately by settings blocks at the edge of the glass.

Drilled and bolted point-fittings, such as shown in Figure 15b–d, are made by means of metal bolts and holes in the glass. These holes can either be made by means of cylindrical (Figure 15b), countersunk (Figure 15c), or

Figure 14 Examples of point-fittings in glass façade. (a) Clamped point-fitting, (b) drilled point-fitting. Source: Photos C. Louter.

Figure 15 Schematic overview of point fittings for glazing. (a) Clamped, (b) cylindrically drilled, (c) countersunk, and (d) undercut.

undercut drillings (Figure 15d), preferably followed by grinding and polishing of their perimeters. The bolt is positioned into the drilled hole and fixes the glass panel to the substructure. These point-fittings are suited to carry out-of-plane loads, but can carry only limited in-plane loads. To avoid direct contact between the bolt and the glass, often bushings (e.g. nylon, pure aluminum) or mortars are applied. Furthermore, since these point-fittings often impose a relatively high local stress at the perimeter of the hole in the glass, the use of heat-treated glass is commonly required.

Another important aspect is that free rotation of the point-fittings should be provided to prevent high stress from concentrating at the point-fitting when the glass panel is bending because of out-of-plane loads. This

can be achieved by means of articulated bolts. Furthermore, to allow (thermal) movement differences between the glass panel and the supporting substructure, oversized or slotted holes should be provided at the bolt-connection to the substructure (Figure 16). These oversized and slotted connections allow for in-plane movement of the panel.

5.2.2 Linearly Supported Façade Glazing

Another example of mechanical connections can be found in façade panels that are clamped in a supporting frame at the perimeter of the glass. The out-of-plane loads on such panels are transferred to the (metal) support frame in a linear manner through contact pressure at the glass surface. To avoid direct contact between

Figure 16 Schematic overview of required allowable in-plane movements of point-fixed façade panel.

the glass surface and the frame, a gasket (e.g. EPDM) is commonly applied. The in-plane loads, however, are not transferred linearly, but by contact pressure through settings blocks at the (bottom) edge of the glass panel.

5.2.3 Through-Bolt Point Connections for High-Force Transfer

The through-bolt connection type [2] is meant for transferring high in-plane forces (Figure 17). It is typically found in structural glass beams and fins, either to connect to the surrounding structure or to join beam segments. The connection consists of a bolt/pin that is inserted in

a hole in the glass and transfers the force between the glass and two outside metal plates. The bolt itself is mostly loaded in shear whereas the forces are transferred to the steel and the glass through contact pressure at the hole perimeter. To avoid direct contact between the bolt and the glass, a bushing is provided around the bolt. For laminated glass, for which the holes in the individual sheets are drilled prior to the lamination process, often an injection mortar is applied to even out any alignment differences between the hole edges. But the main drawback of this connection type is that it requires drilling of the glass, which causes local damage and consequent glass strength reduction at the perimeter of the bore hole. Combined with the localized force transfer, which causes high peak stresses at the (weakened) perimeter of the bore hole, bolted connections in glass are relatively inefficient.

5.2.4 Friction Connections

Friction is involved in the last type of mechanical connection to be discussed here, which also makes use of a bolt that is inserted in a hole in the glass. However, the purpose of the bolt is to clamp tightly two outer metal plates to the glass (Figure 18). The bolt is torqued to a level such that sufficient surface friction is generated to transfer in-plane forces. The hole in the glass is oversized and the bolt does not transfer forces to its edge. Between the steel clamping plates and the glass, friction-enhancing materials could be provided. For laminated glass, a local rigid insert should be provided between the individual glass sheets to avoid creep of the polymer interlayer that would cause loss of prestress in the bolt or fracture of the glass. Friction connections are typically applied for transferring high in-plane forces and can be found in segmented glass beams (Figure 3) or segmented glass façade fins.

Figure 17 Through-bolt connection. For laminated glass alternative, see [2]. Source: Drawing based on [2].

Figure 18 Friction grip connection. For laminated glass alternative, see [2]. Source: Drawing based on [2].

5.3 Adhesive Connections

5.3.1 Overview

Adhesive connections can appear in different geometries, such as linear, point, and large area. They are attracting significant interest in structural glass engineering as they have several potential advantages over mechanical and, in particular, over bolted connections [16]. The main benefit is that no glass drilling is involved – thereby avoiding local weakening of the glass – and that the forces are spread over a relatively large bond area, which implies that the associated stress is reduced. Among structural adhesives such as epoxy, acrylic, polyurethane, and silicone, the last is rather flexible and commonly used for Structural Sealant Glazing (SSG) systems whereas the others – especially the epoxy and acrylic adhesives – can provide very strong and rigid connections. In addition, adhesives such as transparent structural silicone adhesive foil or the aforementioned ionomer interlayer are gaining interest for bonding metal components to glass through an autoclave lamination process [17]. An overview and broad screening of adhesives for glass-metal bonding is provided in [18].

With the exception of SSG systems, however, uncertainties in quality control, durability, and long-term performance hinder the wide application of adhesives in glass structures. These uncertainties often cause restrictions by authorities who generally require additional mechanical connections. This especially applies to permanent loads, such as dead loads of panels.

Furthermore, adhesive connections raise some specific questions. Because adhesives are viscoelastic substances, their structural response depends on load duration and temperature. Long-term loading causes creep/relaxation, whereas increasing the temperature generally leads to a reduction in shear modulus. Furthermore, adhesive connections are preferably loaded in shear while peel forces

should be kept to a minimum. Especially for linear adhesive connections, the stress induced by thermal expansion differences between the adherents should be carefully taken into account. Additionally, the design of adhesive connections cannot rely on a calculation of the average stress in the adhesive bond (Force/Area) because local stress concentrations within it govern the strength of the connection. Finally, from a practical point of view, adhesive connections are generally and preferably not executed on-site, but pre-executed in a protected environment (factory) to keep the bond surface clean and to perform the specific surface pretreatments that are generally required to obtain proper adhesion.

5.3.2 Linear Adhesive Connections in SSG Systems

Linear adhesive connections are typically applied in SSG systems for creating glass curtain wall façades. In an SSG system, the glass panels are bonded in the factory by means of a structural silicone to a metal subframe. After curing of the adhesive, the metal frame and the glass panel as a whole are transported to the building site, hoisted in place, and mechanically anchored to the building structure. The linear structural silicone connection is intended to carry the out-of-plane loads on the glass panel, whereas the dead load of the glass panel is often carried by mechanical supports (at the lower glass edge).

Structural silicones basically exist as one- or two-component products, which cure with air moisture or by a chemical reaction between a base component and a catalyst, respectively. Structural silicone adhesives typically have a rather low Young's modulus of elasticity ($E = 1\text{--}2\text{ MPa}$ [19]) and exhibit rather low tensile and shear strengths (a typical design stress is around 140 kPa, although ultimate tensile stresses can reach between 1 and 2 MPa [20]). They are typically applied in thicknesses of 6–20 mm and with a thickness-to-width ratio in the

1 : 1 to 1 : 4 range [2]. Thanks to their large thickness and low E -modulus, silicone joints are rather flexible, which is beneficial for compensating for thermal expansion differences between the glass and the metal subframe.

Even under clean conditions, primers are often required to promote adhesion whereas surface coatings on the adherents are preferably avoided as they may reduce it. Furthermore, for structural silicones, it is important to check their chemical compatibility with the materials with which they are in contact, such as EPDM gaskets, interlayers in laminated glass, and settings blocks, as these polymeric materials may cause their discoloration and degradation.

In Europe, silicone adhesives applied in structural applications must be approved by means of a European Technical Assessment (ETA). For this purpose, the European Organization for Technical Assessment (EOTA) provides a European Technical Assessment Guideline (ETAG), namely ETAG 002 for Structural Sealant Glazing Kits, which consists of three parts [21]. In these ETAG documents, requirements and testing procedures – such as tensile, shear, durability, and compatibility tests – are provided to which the structural silicone should comply in order to receive CE-marking.

5.3.3 Adhesive Point Connections

A promising alternative for hole drilling and mechanical point-fittings in façade glazing is to bond adhesively a metal puck or connector to the surface of the glass and connect it mechanically to the substructure. Epoxies and acrylates are often used for these kinds of point connections. These adhesives are typically applied in thicknesses in the range of 0.1–3 mm, which guarantees a stiff connection between the glass and the metal connector. Also silicone and ionomer foil adhesives are gaining interest for creating adhesively bonded point-fixings [17, 18, 22, 23].

Although several (research) projects demonstrate the potential of adhesively bonded point connections, their application in practice is currently limited by the aforementioned uncertainties in durability and long-term behavior of the adhesive. Research nonetheless continues to push forward the field of adhesive point connections in structural glass engineering.

5.3.4 Large-Area Adhesive Bonds

Occasionally, large-area adhesive bonds are applied for connecting glass beams to glass columns in portals (Figure 19), which is typically done by means of multilayer laminated glass components [1]. At the intersection between the glass beam and column, the outer glass layers of the beam are stopped short of the end of the beam. For the glass column, the opposite is done, so that a “spliced” connection is made in which the glass beam is inserted into the glass column, as

indicated in Figure 19a. The inverse, as indicated in Figure 19b, is also possible. Alternatively, glass patch plates can be applied, as indicated in Figure 19c, to overlap and connect the inner layer of both the beam and the column. In both cases, transparent setting blocks are positioned between the glass edges of the column and the beam to carry the vertical forces and to prevent direct glass-to-glass contact. At the intersection/overlap of the beam and column, the gap between the glass layers is sealed along the edges and filled with a transparent resin or acrylate adhesive. This chemical is then commonly exposed to a UV-light source which triggers its polymerization. As such, a fully transparent joint is created between the glass beam and glass column.

A second application of large-area bonds can be found in splice-laminated large-span glass beams, fins, or façade panels. In these beam/fin/panel configurations, one creates large-span glass components by laminating several shorter glass segments in overlap (Figure 20) [24]. The individual segments are joined by means of polymer interlayer sheets and are laminated through an autoclave lamination cycle. In the finished product, all interaction between the glass segments is provided through the large-area interlayer bond. This specific technique enables the fabrication of oversized glass components making use of regularly sized glass panels, which may be attractive from a practical and/or economical point of view.

6 Perspectives

Notwithstanding what has already been achieved in structural and architectural applications of glass, a diversity of further exciting developments is currently being explored in research, or already making its way into construction practice [25]. These innovations are likely to enhance the structural and architectural possibilities of glass even further in the (near) future, and are (briefly) discussed in the following subsections.

6.1 Glass Sheet Size

The standard maximum size of a glass sheet for a long time has been 6.00×3.21 m. The width was limited by float-line dimensions, the length by handling and shipping standards and constraints. The glass processing facilities have also been adjusted to this maximum size, or often smaller. This situation changed about halfway the first decade of the twenty-first century when float glass of up to 18 m length became available (see [25] for example applications). Autoclaves and prestressing ovens were also updated to be able to laminate and

Figure 19 Spliced beam-column connections. (a–c) Principles, based on [1]; (d and e) applications in the Buchanan Street Underground metro station entrance, Glasgow; Dewhurst Macfarlane & Partners. Source: Photo C. Louter.

Figure 20 Splice-laminated large-span (21 m) glass beam, (a) overall view and (b) close-up, demonstrated by Glas Trösch/Euroglas at GlasTec 2010 [24].

thermally prestress those sizes. Since then, the number of manufacturers and processors able to handle 6+ m sizes has grown steadily, as has the number of projects in which such sheets have been applied [49]. Currently, glass sheet sizes between 6 and 12 m length are no longer extremely rare although lengths of more than approximately 12 m are still unique. This may be due not only to the cost of such elements in the initial construction, but also to the financial in-service risk. Replacing such an element in case of (accidental) damage is expensive, time consuming, and intrusive to the particular structure. Additional care and consideration in design and construction is therefore required.

6.2 Cold Bending

Developments in architecture since the end of the twentieth century have hugely increased the popularity of non-orthogonal shapes. Curved glass components for building applications are traditionally produced by means of a hot-bending process. However, this technique has some disadvantages, such as high costs for molding, high energy consumption, inefficiency in transport of the curved components, and risk of optical distortions. Therefore, alternative cold bending techniques are currently gaining significant interest for building applications [26].

With these techniques, one “simply” elastically curves, warps, or twists flat-glass panels at ambient temperature to the desired shape and subsequently fixes them into position. This solution is economical as it does not require expensive molding or high energy consumption for heating the glass. Furthermore, optical distortions are minimized and the resulting reflections are smooth. The degree of curvature is more restricted than for hot bent glass, however, because of the applied permanent

bending stress on the glass. Therefore, cold bent glass generally requires the use of fully tempered glass, which has enhanced strength and does not suffer from stress corrosion phenomena as long as the compressive prestress is not overcome. Additionally, the thinnest possible glass panel is generally adopted to minimize the bending stress. Minimal curvatures of $1500t$, with t = glass thickness are generally accepted, but in cases bending radii as small as 3.0 m can be applied.

Cold bending by assembly is most common. In this respect, an often applied strategy is to curve flat-glass panels over a pre-curved (linear) subframe and to clamp them into position. This can also be done using special devices that pre-curve the glass panel airborne before mounting it to the (curved) substructure [27]. Another strategy concerns mounting flat-glass panels by means of point-fixings and subsequently forcing one or multiple point-fixings out-of-plane to create the curved glass surface. Though less commonly applied, an alternative *cold bending by assembly* strategy is to assemble flat-glass panels to a linear subframe and to curve/warp the assembly as a whole.

Yet another method is the *cold bending lamination process*. Several glass layers are bent to the desired curvature, stacked with intermediate interlayers and subsequently laminated by means of an autoclave lamination procedure during which the interlayers adhesively bond the glass layers. Thanks to their shear stiffness, the interlayers are able to keep the glass layers in the curved position. However, specific points of attention are the initial springback upon release of the laminate and the creep/relaxation response of the interlayer over time.

Several projects involving cold bending of glass have been completed over the recent past years (Figure 21). Furthermore, an increasing number of academic studies

Figure 21 Curved glass envelope realized by means of cold bent glass, Strasbourg railway station, France. Source: Photo M. Denancé.

are advancing on this topic [28–30], focusing on issues such as the springback relaxation effects of glass panels produced by a cold bending lamination process and the buckling behavior of cold bent glass panels.

6.3 Custom Cast Glass

Casted glass blocks for semitransparent applications (mostly partitioning walls) have been common for considerable time and are not of particular architectural quality. However, occasionally, projects arise for which high-quality custom cast glass elements are used to create striking visual results. A recent example is the Crystal Houses project in Amsterdam, the Netherlands [31, 32], which features a traditional Dutch brickwork and timber façade having been remade completely in glass, with cast bricks and window frames (Figure 22). Previous projects included the March 11 memorial in Madrid, Spain, and the Ice Falls entrance to the Hearst Tower in New York, USA. Such projects, however, seem to remain one-offs, rather than become main stream.

6.4 Adhesive Point Connections

Adhesive bonds, discussed in Section 5.3, particularly high-transparent point connections, are likely to be pushed by architects because of their high aesthetical quality. It may be expected that such connections will become the standard in due time. Extensive testing on reliability, failure behavior, and durability, as well as

further showcase projects are probably required to gain acceptance from authorities.

6.5 Hybrid Glass Components

A steadily increasing trend exists in the development of hybrid glass components that can provide several advantages over common structural glass components [33, 34]. These components consist of glass – typically as the main load-carrying material – and an additive material (e.g. metal, timber, carbon fiber reinforced polymer, glass fiber reinforced polymer) which are joined by means of an adhesive bond or a bolted connection. The hybrid components are intended to outperform common structural glass components by providing enhanced pre-fracture performance, postfracture performance, or a combination of both.

In terms of enhanced *pre-fracture* performance, a hybrid glass component can provide increased in-plane or out-of-plane bending stiffness. For instance, a hybrid glass sandwich component that consists of two outer glass panels and an adhesively bonded inner spacer can show superior out-of-plane bending stiffness compared to a regular glass panel. Furthermore, hybrid glass beams consisting of a glass web and additional flanges made of steel or timber show enhanced (out-of-plane) lateral torsional buckling stability [35] (Figure 23).

In terms of enhanced *postfracture* performance, hybrid glass components can provide significant postfracture strength and redundancy. One can achieve this

Figure 22 Cast glass block facade, Crystal Houses, Amsterdam, (a) overview, (b) close-up; MVRDV, ABT, TU Delft. Source: Photo F. Oikonomopoulou [31, 32].

postfracture strength by bonding additional reinforcement at the tensile side of the glass component. In case of glass fracture, the reinforcement will bridge the crack(s) in the glass and will carry the tensile force. This

Figure 23 Glass beam with adhesively bonded steel flanges [33].

postfracture load-carrying mechanism provides significant redundancy to the structural glass components and enables them, if cracked, to carry significant load. The validity of this concept has been demonstrated both for structural glass beams with reinforcement bonded at the tensile edge, e.g. [13] (Figure 24), and for glass panels with reinforcement mesh laminated between the glass layers [36] (Figure 25).

Finally, in terms of enhanced *pre- and postfracture* performances, it is worth to also mention post-tensioned glass beams [34]. In these beams, a compressive prestress is imposed by means of (steel) post-tensioning tendons which are either mechanically anchored at the glass beam ends or adhesively bonded along the beam length [37]. This compressive prestress enhances the tensile (bending) strength of the glass and thus increases the initial fracture strength of the glass beam. Furthermore, after glass

Figure 25 Metal wire mesh or perforated thin metal plate reinforcement embedded in the interlayer of laminated glass [36]. (a) Overview of reinforced laminated glass samples, (b) laminated glass with and without reinforcement.

fracture, the post-tensioning tendons act similarly as the aforementioned reinforcement in reinforced glass beams, thereby providing significant postfracture strength and ductility.

6.6 Smart Glass

A development not directly structural, but nevertheless very important to the use of glass in buildings, is the integration of functionalities to increase performance, mainly related to indoor climate and comfort. Besides selective solar reflective coatings with increasing efficiency, step-less switchable glazing from transparent to opaque is gaining ground [38]. A few years ago, translucent photovoltaic cells on glass were introduced, see e.g. [39]. Now, a window is under development that combines switchability and power generation [40]. Such innovations will further stimulate the use of glass, and are likely to be combined with structural applications as well.

6.7 Chemical Prestressing

A technique that has been known for a significant time and one that may have particular structural use is chemical prestressing. Like thermal prestressing, it results in a compressive prestress in the glass surface. However, this process is based on ion-exchange of surface ions. By submersing a glass sheet in a potassium salt solution at elevated temperature, Na^+ ions in the glass surface are replaced by larger K^+ ions from the bath. This process, known as chemical prestressing, also induces compressive stresses in the glass surface. However, the stress profile through the thickness is different (Figure 10). Very high maximum surface stresses can be reached depending on the submersion time. According to EN 12337-1 [41], the characteristic bending tensile stress of chemically strengthened float glass is 150 MPa (including inherent strength). But the compressive layer is much thinner, and the tensile stress in the inner glass is much lower. Therefore, this prestressing method also induces much less elastic strain energy into the glass than thermal prestressing. As a consequence, chemically prestressed glass does not break into small fragments and can be cut after prestressing.

The thin compressive layer is often considered a weak point of chemically prestressed glass, as it can be penetrated by a scratch, leaving the inner glass (already under tension) exposed. On the other hand, the surface of chemically prestressed glass is harder to scratch, with the Vickers hardness reaching 625 opposed to 550 for annealed glass [42]. Extensive research into the structural behavior of chemically prestressed glass for application in buildings has not been performed. As it is expensive, relatively unknown and comes with the size limitations of

the available salt baths, it is still rarely applied in buildings. Nevertheless, the high tensile resistance in combination with favorable fracture pattern and lack of optical distortion (present in thermal prestressed glass) may instigate more extensive use in buildings in the future.

6.8 Thin Glass

The introduction of smart phones and tablets over the last decade stimulated the development of strong, but extremely thin glasses (typically 0.55–2.0 mm [43]). Trade names include Gorilla Glass by Corning, Dragontrail by AGC, and Xensation by Schott AG. These are not soda-lime silicate, but alkali aluminosilicate glasses. Different production processes are used besides float processes, such as the vertical overflow fusion process. These glasses are chemically prestressed and it is claimed surface compression stresses of over 900 MPa can be obtained, as well as a Vickers hardness of 600–700 [44–46]. Prices and sizes seem to be limiting application in construction, also because for most applications, the panel stiffness will become governing once such extreme strengths are obtained. Then, the thinness is not beneficial anymore. Nevertheless, the possibilities for such glasses are being explored [47]. They may be beneficial particularly in moving building parts such as elevators and retractable roofs.

6.9 3-D Printing of Glass

Additive manufacturing is being explored in all segments of the manufacturing industry, in- and outside of construction. A wide range of materials can be printed. In 2015, an experimental 3-D glass printing facility was presented by MIT [48]. For now, this facility is capable of printing relatively small art-like objects. Although many issues may need to be solved in terms of strength, annealing, optical quality, or size, it is not unthinkable some special glass parts of a structure will be printed in the future.

9.2

Tempered and Laminated Glazing for Cars

René Gy

Saint-Gobain Recherche, Aubervilliers, France

1 Introduction

Conciliating outside vision with protection against bad weather has long made glass an indispensable material in transportation means. Small flat panels produced by either the crown or mantle processes (Chapter 10.9) were thus early used for the windows of stagecoaches, ships, or train cars. Following the development of direct flat-glass production in the early twentieth century (Chapter 1.4), however, the expansion of the automobile and aircraft industries has put much more stringent constraints on the glass material, first in terms of safety and now of various added functionalities. The goal of this chapter is to describe how these needs are satisfied. We will begin with a brief history of the evolution of car glazing. The various functions of glazing will then be described in relation to vision, safety, heat, noise, information display, and recycling. Manufacturing will then be described in terms of cutting, screen printing, forming, and strengthening. Finally, the new challenges to be met in a near future will be described.

Here, the focus is put on the car market because of its sheer size. But it goes without saying that similar glass products are used in trucks, buses, trains, trams, boats, or aircrafts although the relevant requirements may differ. For instance, whereas a defrosting windshield is desirable in a passenger car, it is absolutely needed in an aircraft cockpit. Likewise, the high-strength requirement for cockpits translate into thicker glazing compared to cars. Glazing is also thicker for boats, for fire-resistance reasons, and even thicker for high-safety, bullet-proof vehicles. On the other hand, styling constraints are of uttermost importance for cars. The manufacturing technologies may also differ: for buses, the glass parts are

much larger than for cars but the series are shorter so that less emphasis is put on throughput and more time can be spent on the forming process. Regardless of such specific features, all these applications are relying on the fundamental advances made in glass science and technology. These are in particular described in the chapters on flat-glass production (Chapter 1.4), physical and chemical strengthening (Chapter 3.12), coloration (Chapter 6.2), electronic displays (Chapter 6.9), and glass recycling (Chapter 9.8), where the relevant background information will be found.

2 A Brief History from the Early Twentieth Century to Today's Huge Market

The first automotive cars had no windows, or windows made of single monolithic non-strengthened glasses, which could be the cause of many serious injuries in case of accidents, but two kinds of safety glazing quickly emerged: first laminated and then thermally tempered glass.

The early history of laminated glass is reported in [1]. In 1903, the chemist Édouard Benedictus (1878–1930) observed in his laboratory that, when accidentally dropped on the floor, a glass flask that had contained cellulose nitrate [$C_6H_8N_2O_9$] was broken but the glass pieces held together, thanks to coated plastic inside the bottle. He filed a patent [2] and founded the Société du Verre Triplex in 1911 for the fabrication of safety laminated glazing. As early as 1919, some of the Ford model T cars featured a windshield made of such safety glass and, according to the National Glass Association, within 10 years the Ford Motors company ordered the use of laminated glass on all of its vehicles. The plastic polyvinyl

Reviewers: F. Creuzet, Saint-Gobain Recherche, Aubervilliers, France
E. Mimoun, Saint-Gobain Recherche, Aubervilliers, France

butyral (PVB) $[(C_8H_{14}O_2)_n]$ was invented later in 1927 [3]. It had many advantages over cellulose nitrate, not only in terms of safety but also superior in optics, as less prone to color change over aging so that it was used as early as 1941 in virtually all laminated safety glazing [4].

As for thermal strengthening of glass, it had been known since the seventeenth century through Prince Rupert's drops (Chapter 10.11) but was not applied industrially until 1874 when Francois Royer de la Bastie (1830–1901) quenched hot glass in grease or oil to improve the mechanical resistance of glass objects such as goblets [5]. In Germany, another tempering process better suited to flat panels was invented by Frederick Siemens (1826–1904, cf. Chapter 10.9) who strengthened glass in 1877 by pressing it in between cold molds [6]. Glass tempering with impinging air jets was eventually invented at Saint-Gobain in the 1920s [7], resulting in cost reduction and in improved shape and surface finish compared to previous processes. As a result, this so-called "Securit" glazing took over laminated safety glass in European automobiles in the 1930s – windshield included –, whereas in the United States, it was not until the early 1960s that the use of tempered glass for side window (sidelite) and rear window (backlite) was generalized to ensure lower costs. Tempered glass was not used for windshields in the United States, however, whereas in European countries, safety concerns eventually led in the 1970s and early 1980s to prohibit it and to impose laminated glass instead.

The first automobiles had only flat windows. To improve the design of the most advanced cars, windshields were then made up of two flat parts before it became possible to produce a curved surface as first made in 1947 for the Studebaker Starlight coupe. Curved glazing then became more and more common for all car windows even down to the lower segments of the market. The first car openable sunroof is reported to date back to 1937, but glazed sunroofs only appeared in the mid-1970s.

Today's market for car glass is huge. Glazing for transportation accounted for about 10% (15% in Europe) of the 6 billion m^2 of flat glass produced worldwide in 2010, the overwhelming majority of which having being supplied to automotive original equipment manufacturers (OEM). In the European Union, about 50 factories produce automotive windscreens, sidelites, and backlites. These plants are usually located not far from both car assembly plants (to meet very short delivery time requirements) and primary float lines (to optimize logistics and reduce transportation costs and environmental footprint). In value, the share of automotive glass is even higher, representing around 25% of the global market for the end uses of flat glass, which was estimated at more than 50 billion € in 2010. This figure is expected to double by 2018 [8]. In other words, the secondary transformation industry brings much more

added value to the automotive glazing market than to the two other main end-markets for flat glass, namely, construction building and electronic displays.

3 Glazing Functions

3.1 Vision

Of course, cars have windows because the driver needs – and the passengers want – to see through the cabin that protects them from weather conditions. The ECE R43 European regulation specifies that, as determined from ISO 3538 testing, light transmission be higher than 70% in windshield and front sidelites involved in driving. For the windshield, or at least its vision area, other requirements concern optical distortion and the so-called ghost images. Such images, mostly visible at night, are optical effects caused by the windshield curvature, its oblique inclination, and internal reflections of light at the glass–air interfaces (Figure 1). Optical distortion may in addition arise, especially when laminated windshields are mounted with a low angle over the horizontal or for sidelites when the direction of sight lies at a low grazing angle. Moreover, the optical quality of laminated windshield made with flat glasses from a poorly controlled float glass process can be impaired. The primary float glass surface imperfections (cf. Chapter 1.4) may, after lamination, result in dioptric defects, also causing some distortion in light transmission through the windshield at low grazing angle.

Windshields and backlites have wipers to remove rain droplets or snow flakes and to clean the smudge, dust, or insects that also hinder the visibility. Nowadays, wiper technology can meet most of the usual glazing curvatures and high-speed aerodynamic requirements. Defogging is

Figure 1 Optical sketch for the formation of the *ghost* image through a windshield of thickness t , with curvature radius R . The driver's eye perceives one ray from a light source, impinging on the windshield under incidence i , and another one, due to internal reflections within the glazing, coming from another incidence, shifted by a small angle s . Source: Adapted from [9].

quite efficiently done with the air-conditioning system of the car, whereas the backlite has for a long time been equipped with printed conductive lines connected to the electric power supply of the car through screen-printed bus-bars (made of the same electrically conductive glass frit as the lines) on which metallic connectors are soldered. Heating laminated windshields, for some few high-end cars, used to be done with very tiny (but still visible) conductive metallic wires, embedded into the polymeric interlayer. Nowadays, windshields can be heated with silver-based transparent conductive thin film [10]. Such heating glazing technology, which ensures much quicker and more comfortable defrosting, is energy-efficient and especially suited for electric vehicles.

Making car windows out of clear plastic without using glass would enable to design more complex shapes and allow for more easy integration in the car body. But current transparent organic materials like acrylic or polycarbonate can hardly be used. They would quickly suffer a loss of clarity from the friction of their surface – especially for the windshield and backlite – against the wipers and from other damages caused by flying dust; and, for the sidelites, during up/down movement. A high enough hardness is a key feature: the ECE R43 European regulation requires passing abrasion tests such that currently transparent polymers with the best available hard coatings can only be used in a limited number of cases, like small fixed quarterlite. It could even be argued that the silicate glass surface strength is hardly sufficient: an examination of the surface of the original windshield from a high-mileage car reveals numerous microscopic craters and scratches that results from very small impacts and from friction with the wipers (Figure 2). These act as

light diffusers that may deteriorate the comfort of driving, even with a clean windshield, especially at night.

There are no specifications for the light transmission of the glazed parts not involved in driving. Actually, passengers may also want to enjoy more thermal comfort and some privacy: these requirements have driven the development by OEM of flat glass with light transmission as low as 10% for a 3 mm thickness. Such a level is obtained through high doping of the usual soda-lime glass with up to a few % of colorants like iron. For retrofit market, application of tinted polymer films is common.

3.2 Safety

Along with vision, safety is a primary requirement for car glass. For tempered parts, it is ensured not only by the higher strength of the glass but also, and more importantly, by the fine dicing produced upon breakage (Figure 3a). The small fragments are indeed much less dangerous than the long and sharp pieces that might otherwise fly or be left salient during a car crash. The ECE R43 European regulation requires that a fragmentation test upon breakage be passed: for a glass thickness lower than 3.5 mm, there must be between 40 and 450 fragments in any 5 cm-sided square. That the fragments tend to stick to one another and stay in place after breakage is a big drawback for tempered-glass windshields, however, which would make vision impossible. In contrast, even though smaller or slower gravels may produce cracks in a laminated glass, their number and size are small enough so that vision is not severely impaired after an impact (Figure 3b). Various other mechanical tests aiming at guarantying safety are included in the regulations: ball

drop tests, penetration resistance tests, head-form impact test for assessing brain injury and laceration risks, etc. These tests as well as medical and forensic studies [11, 12] highlight the superiority of laminated glass compared to tempered glass from the safety point of view in case of a car accident and especially of passenger ejection in roll-overs. But laminated sidelites are found only in a limited portion of the high-end segment of the car market because of the cost issue.

A higher resistance to fracture also makes laminated glass superior from a security point of view. A tempered window is a weak point from where thieves can easily steal something in a car. A laminated glazing gives them a much harder job.

3.3 Car Design, Integration to Car Body, and Systems

A nice design is critical for a car to become a commercial success. A key feature of today's designs is the smooth and continuous integration of the glazing. The better-looking integration ensured by the *flush* design became possible more than 30 years ago when the old mounting process of framing with thick rubber gaskets was progressively replaced by the now universal gluing technology whereby polyurethane resins directly bond the glass to the car body. Screen-printed, highly opaque black enamel is provided on the periphery of glass and serves as a mask for the glue for aesthetic reasons and for protection against UV aging. The requirement that the glazing fits to the car as continuously and naturally as possible translates into increasingly tight geometric tolerances for the shape of the complex curvature of the glass and into a thorough control of its optical aspect seen in reflection both from

the outside of the vehicle and under low incidence. To meet these high-quality criteria, the bending process of flat glass has made important progress in the past decades. Still, some of the car designers' ideas are not yet cost-effectively doable with glass, and/or at the required quality level.

Because of its suboptimal aesthetic match to the different car colors, it would be desirable to change the greenish color of the iron-doped flat glass currently used for the automotive application for a more neutral gray color. Moreover, the inside lining of the car would look better, when seen from outside or from inside at daylight, through a glass with a more neutral color. But gray glasses keeping the same anti-solar efficiency are not available at the same low cost as iron-doped glasses.

Design is not the only driver for the ever tighter integration of the glazing into the car body. For car manufacturers, reducing the number of parts and operations on the assembly line is a lever for cost reduction. Therefore, there is a trend for car-glazing manufacturers to bring more value to their products by adding on as much operations, or other materials, as possible, everything that can be done at the end of the glazing fabrication more efficiently than later on the car assembly line. Soldering of electric connectors and deposition of adhesion primers are basic examples. This trend has also led to the development of a number of *post glass* operations at the car-glass manufacturer or at the specialized-part supplier. Periphery joins or other plastics (polyurethane mostly) add-ons are commonly extruded, or injection-molded on the glazing, or at its periphery. The *encapsulation* process involves the injection molding of a polymer trim, shaped precisely to fit the vehicle body, to the periphery of the glazing. It also provides the opportunity to incorporate

additional styling and technological features such as metallic parts (pre mounting), antennas, or sensors. This evolution can go as far as supplying a full system: a back door, an openable sunroof, etc. The case of sunroofs is interesting as it highlights another aspect of glass: as a material, it is hardly stiff enough for the application, especially for complying with the opening mechanism, and upon high-speed driving, the slight inside pressure increase may trigger an upward bowing that is unwanted mostly because of aerodynamics and perceived quality issues. Therefore, metallic reinforcing bars may have to be glued on the glass roofs, or are embedded into the plastic during the encapsulation step. Generally speaking, this lack of stiffness is a concern for parts that are not very deeply curved or cannot be glued on the car body, especially because of the general trend toward larger, panoramic, and thinner glazing.

3.4 Thermal Comfort

One of the primary reasons for using tinted glass for car glazing is to reduce transmission of solar heat to the vehicle interior. Doping glass with transition elements, especially iron, and controlling their oxidation state allow for enhanced absorption in the near-infrared (IR) range (Figure 4). The soda-lime glass composition for automotive applications has been optimized in this way so as to reduce as much as possible the direct solar input. For the windshield, the attainable heat barrier from the glass composition alone is limited because of the 70% visible light transmittance requirement. An even better selectivity is obtained, thanks to the combination of tinted glass with a transparent solar control thin film on one of the two glasses of the windshield, or within the polymeric interlayer. Such high-performance solar-control glazing solutions can reduce heat penetration in vehicles by more

than 25% and the interior cabin temperatures by 7 or 8 °C [13]. This technology is especially valuable for electric vehicles, for which savings on the energy consumption from the air-conditioning system are welcomed, as they readily translate into an increase of the vehicle range autonomy. For nonelectric vehicles, it is also interesting as any reduction on the load work on the air-conditioning is a way of lowering the CO₂ emissions.

There is also an issue with cold climate comfort: cars tend to have larger and larger panoramic glass sunroofs, the inner side of such a large glazing takes advantage of a low-emissivity coating (Chapter 6.8), which can help reduce an otherwise too strong radiative cooling from the inside.

3.5 Acoustic Comfort

The noise perceived in a car may originate not only from the engine, power train, and tire friction with the road but also from aerodynamic interactions with the car body. Glazing is a preferred path for noise ingress into the vehicle interior. For example, at high speed, the wind turbulent pressure fluctuations against the glazing make it radiate noise inside the car. On the other hand, reductions of the car fuel consumption and greenhouse gas emission are drivers for more lightweight cars, and more lightweight glazing in particular. This makes it more difficult to improve acoustic comfort in the car. From an acoustic standpoint, a laminated glazing performs better than a monolithic tempered glazing of the same weight because some vibration damping takes place within the PVB itself, which can even be enhanced further (Figure 5) with special multi-ply high-damping *acoustic* PVB [15], resulting in insulation improvement of about 5 dB, which is quite noticeable to the ear [16].

Figure 4 Effect of iron doping on the transmission of near-infrared radiation by a 3.85 mm thick glass: (a) solar irradiance; (b) regular glass; (c) auto glass (about 0.6% Fe_xO_y). Source: Courtesy O. Cintora, Saint-Gobain Recherche.

Figure 5 Effect of glass lamination with PVB on sound-transmission loss at 20 °C for a panel size is 47 × 74 cm, from [14].

3.6 Communication, Information Display, and Other Advanced Functions

Nowadays, cars are connected objects so that the glazing has to be a window not only for visible light but also for electromagnetic waves carrying information at the frequencies relevant to radio sets, GPS, telephone, or Wi-Fi, and also to remote-controlled garage doors or toll barriers. Antennas are screen-printed on the backlite, on top of the heating lines, or on other glazing and become virtually invisible to improve the vehicle's profile and reduce noise from wind or vibrations. Glass has fitting dielectric properties ensuring a very good reception quality and a broad bandwidth. On the other hand, windshields featuring electrically conductive transparent thin film may be problematic, which is why a small portion of the glass surface is better left without any film.

Projecting information from the dashboard on the windshield, so as to make it visible by the driver head up, as an image focusing at some distance ahead of the car, has been existing for quite a long time. The head-up display technology originates from the military aircraft industry. The quality of the image is improved, thanks to a special wedge-shaped PVB interlayer [17] in order to eliminate the ghost image issue. This functionality is still limited to a small segment of the automotive market, but in the near future, the windshield will more and more have to be compatible with, or even used as, an information display device for the numerous systems that are now available in order to provide assistance to the driver, especially at night.

3.7 Recycling and Sustainability Issues

Between eight and nine million tons of end-of-life vehicle (ELV) waste is generated each year in the European Union [18]. Glass amounts approximately to 3% of the total weight of a car. Disposal in landfill of waste glass from cars will not be permitted in most European countries as the 2000/53/EC European ELV directive is implemented. In principle, glass is an infinitely recyclable material, but the process of dismantling a car and sorting out the different materials is complex and difficult. For glazing, the strength of the glued bonds to the car body becomes, at that stage, somewhat of an issue. Removing the metallic parts, connectors, etc., is not easy and even more so, separating the PVB that, by the way, is a rather valuable scrap by itself, also susceptible of a recycling process after purification, melting, and reshaping. Even though a limited amount of PVB remaining on the glass fragments is acceptable as it will be burnt in a glass-melting furnace, the as-obtained glass cullet also needs to be refined to be melted again. Still its quality is insufficient for being reused in significant amount in float glass furnaces. It would be compatible with lower-grade glass applications, such as glass wool and probably bottle manufacturing, but the cost of such refined glass cullet from ELV waste remains high. In addition to the above technical challenges in dismantling and separating car glass from other materials, there is also the need to organize cost-efficient supply chains and markets from the thorough collection of ELVs to the mass production of refined glass cullet from ELVs and, eventually, transportation to

glass melting furnaces. But these are high barriers still to overcome before viable circular economic processes can be fully developed.

Besides setting targets for the recycling of ELV, the same European directive also prohibits the use of heavy metals in auto parts. Lead, which was present in the glass frits for enamels and in the alloys for the electrical connection soldering, is no longer used in car glazing. Lead-free technologies have been developed for these applications.

4 Manufacturing

4.1 Cutting/Edge Machining

Car windows are made out of standard size soda-lime silicate glass rectangular panels from the float process, approximately 3 m × 6 m, which are further cut down to smaller rectangular shapes fitting the size of the windows. The big panels may also have previously received any functional thin film coating that must survive the subsequent manufacturing steps. The thickness is around 3 mm or less for glass to be laminated. The glass-cutting process is automated. A sharp tungsten carbide or diamond wheel is first moved onto the glass surface along the curved periphery of the piece to be cut, so as to create a continuous blind surface crack a few hundreds of microns deep. Following scoring, a breaking bar moves upward, from underneath, and drives the propagation of the cracks along the previously scored line under double-torsion loading. A cutting oil is used during scoring to ease the whole process, as it prevents moisture from the environment from interacting too much with the cracks and, thus, from attenuating the scoring residual stress field [19]. The outer part is trimmed, thanks to additional straight lines scored up to the edges of the initial rectangular plate in the main directions of the curved line to ensure trims as straight as possible for easier breaking. Trims are recovered to be recycled into a float furnace.

Coming right after cutting, edge working serves a dual purpose: car glazing generally has apparent edges that should not be sharp for safety and aesthetic reasons. A grinding wheel, featuring diamond grits held together with a metallic bond, whose edge has a concave C-shape, runs along the edge until the desired shape and smoothness are obtained. A grinding fluid is used for cooling, lubricating, and continuously cleaning the wheel. Drillings are also done according to the customer's requirements, for example, for a movable sidelite or for the wiper axis of the backlite. Finally, the parts go through a washing machine to remove all the remaining debris and traces of cutting oil.

4.2 Screen Printing

The aforementioned black enamel is a paint obtained by mixing a low-temperature melting glass frit, mineral pigments, and an organic medium. Its rheology is adapted for a screen-printing process (serigraphy). As said, the black enamel serves a design purpose and protection of the gluing. The same screen printing step is also used to print some mandatory information, car manufacturer logo, and details about the glazing specification and production traceability. The freshly painted parts have to be dried online in a continuous tunnel oven. When required, a conductive circuit (another frit paste, highly loaded with silver powder) is also screen-printed on top of the black and on the glass, on the "tin" side of the original float glass. All the remaining organics are removed during the following heating step while the enamel is fired.

4.3 Heating

The glass is heated up to about 650 °C, i.e. about 100 °C above the glass transition, to lower its viscosity down to about 10⁹ Pa·s. This heating takes place continuously in tunnel furnaces. For tempered glass, the parts are conveyed on rollers whereas for laminated glass, they are conveyed pairwise, one on the top of the other, on a moving trail of peripheral frames (Figure 11a). Although the physics of flat glass heating is complex, a very good control of heating is critical for the following forming and strengthening steps. As glass moves, it is exposed on both sides to the IR energy of radiant emitters covering the inner walls of the furnace. Because of the semitransparency of glass in the IR range of the emitters' spectrum, the heat-flux density absorbed strongly depends on furnace temperature and on the thickness and iron content of the glass [20] (Figure 6). The situation is complicated further by the enamel, whose IR properties differ from those of the bare glass and, when present, by any thin film coated on the glass. Radiation is the main contributor to the heating, but heat convection is not negligible (low-emissivity thin-film coated glass may take advantage of reinforced convection heating furnace). Heat transfer by contact with the conveying rollers, which may induce transient glass bowing on the hot rollers and conveying issues in the furnace, has also to be considered. Heating must generally be as homogeneous as possible for tempered parts, but is purposely nonhomogeneous for laminated parts to meet the forming requirements.

4.4 Forming/Strengthening of Tempered Parts

The physics of glass thermal tempering and the associated building up of residual stress in flat glass were understood in the 1970s [21]. Upon symmetric cooling, the

Figure 6 IR absorptance (resp., emittance) of flat glass for different thicknesses t , as a function of furnace (resp., glass) temperature T . Plain lines: 6000 ppm total iron oxide content. Dotted line: 450 ppm total iron oxide content. Source: Courtesy D. Mélite, Saint-Gobain Recherche.

temperature profile across an initially uniformly hot plate quickly becomes roughly parabolic. The parabola then shifts to lower temperatures without changing much its shape until it flattens when room temperature is approached. If the glass is fluid enough when the parabolic temperature profile takes place, the initial phase of the cooling is not accompanied by any thermal stress. Stress would start to appear only when the temperature parabola gets flattened: the core tries to shrink more than the surface, resulting in the well-known surface compressive stress compensated by a tensile core stress. However, according to in situ photoelastic experiments made during cooling through the glass transition range [22, 23], a transient tensile surface stress is observed at the very beginning of the cooling and some compressive surface stress is observed as soon as the core temperature reaches the glass transition range (Figure 7). The former observation is a viscoelastic thermal shock stress, which is all the

more significant that the initial fluidity is low: this explains why too low an initial temperature results in a lower final tempering stress and in frequent breakage at the beginning of tempering. The latter is explained by the steep change in thermal expansion when the glass undergoes the glass transition; this *structural* contribution to the tempering stress is higher for thicker panels whose glass transition takes place at a higher viscosity in view of a lower cooling rate. Nevertheless, the obtained stress profile is roughly parabolic, parallel to the steady-state parabolic temperature profile upon cooling. The magnitude of the residual stress is proportional to the maximum core-surface temperature difference, which scales with the intensity of the cooling and with the glass thickness.

These features explain (i) why it is necessary to heat the glass well above the transition temperature to start with a fluid enough glass; (ii) why the residual stress does not increase further with an initial temperature higher than a certain value, (iii) why glasses with low thermal expansion coefficients, e.g. borosilicates, are unfit for thermal tempering; (iv) why tempering thinner glass requires a larger cooling rate. For car-glass tempering, the typical heat exchange coefficient with impinging air jets must be of the order of $500 \text{ W m}^{-2} \text{ K}^{-1}$ or more and be as homogeneous as possible over both glazing surfaces. These conditions are achieved in carefully designed *quench boxes* where arrays of nozzles, supplied with a high flow rate of cold air from big fans, are blowing at a high speed from a controlled distance onto the glass surfaces. For large parts and thinner glasses, quench boxes must be carefully designed to ensure an efficient evacuation of the very large amount of blown air, which would otherwise become a limiting factor for the heat exchange coefficient or its homogeneity over the surface.

Thermal tempering of thin glass is made even more difficult for other reasons. First, a larger residual stress is required to obtain the same fragment size in a thin glass

Figure 8 Fragmentation of tempered glass as a function of tensile core stress. The numbers refer to the glass thicknesses (mm). Source: Adapted from [24].

as in a thick glass (Figure 8). The size of the fragments comes from the bifurcation length of a through thickness crack, which is the length at which the stress intensity factor for such a crack reaches a critical value. But this stress intensity factor does not depend only on the stress magnitude but also on the thickness itself as explained, for instance, in a recent model of the fragmentation process in tempered glass [25]. Second, as already stated, the structural contribution to the tempering stress is lower for thinner glass. Third, the minimal fluidity needed at the beginning of the cooling is larger because of the

higher cooling rate required. Hence, tempering thinner glass requires a higher initial temperature. But to convey, manipulate, and shape a very hot and thin glass while preserving the geometric and surface quality is a real technological challenge. In industry, it is hardly possible to temper soda-lime silicate glass thinner than 2.5 mm at the required yield and optical quality level. On the other hand, there is no real need for developing further the technology of thermal tempering of very thin glass for automotive application, in spite of the weight that would be saved, since such a thin monolithic glazing would have quite a poor acoustic performance.

The forming of quasi cylindrically shaped tempered sidelite is done online, at the same time as the tempering: upper and lower straight rollers at the exit of the heating furnace are conveying the hot glass trough the quenching boxes without interruption. The outside rollers' bed has the desired cylindrical shape, driving the glasses upward. The forces applied to the glass as its moving direction changes is enough to bend the glass as it is simultaneously quickly cooled down by the air jets [26]. One does conveniently shape adjustments by playing with the non-symmetry of the cooling. This simultaneous forming and bending process is very efficient from an industrial point of view, as the continuous production of sidelites at a rate of more than 20 parts per minute is achievable (Figure 9).

More complex-shaped sidelites and backlites require either sag- or press-bending: before being transferred in the quenching boxes, the hot glass is taken from the rollers and supported at its periphery by a ring mold, while the action of gravity gives the shape. It can also be pressed against a generally convex upper mold. Special contacting materials have to be used to cover the molds, which lie either inside or outside the furnace. The shaped glass is

Figure 9 Sketch of a machine for shaping and simultaneous tempering of sidelites. (10) furnace; (9) conveying roller; (4, 11, 13) shaping rollers; (25) blowing boxes. Source: From patent FR 2549465.

Figure 10 Strain pattern caused by an anisotropic heterogeneity of the residual stress, visible under certain natural light conditions, as a mottled appearance of the tint of the glass; here on a tempered backlite.

then moved and tempered into appropriate quenching boxes. During air blowing, the part is supported on an air-permeable peripheral tool to ensure proper tempering of the edges as well. The tempering tool is given an oscillating lateral movement during air blowing. Because of a small spatial variation of the heat exchange coefficient under the air nozzles of the quench box, there is a slight variation of the degree of tempering. In turn, a slight photoelastic effect may be observed when the glazing is seen under the slightly polarized natural light from a clear sky, as a small portion is reflected back in the direction of the viewer, on the inner glass surface and hence undergoes a slight change of polarization direction upon reflection close to Brewster [27]. The angle at which the glazing is seen, hence its inclination on the car body, has an influence on the perception of this undesirable “strain pattern” of tempered glass (Figure 10), but the lateral back and forth movement of the part in the quench boxes mitigates this effect.

4.5 Forming/Strengthening of Laminated Parts

As already stated, the two glasses for a windshield are heated up together at a temperature above 600 °C, one lying on top of the other and supported on their periphery on an annular mold. An anti-sticking agent is provided in between the two to prevent any risk of sticking when the glasses get softened into the furnace. The force driving the shaping comes from gravity (sag bend) or, once softened enough, from mechanically pressing against another mold (press bend). One key feature of the process for forming of glasses for the manufacturing of laminated parts is the simultaneous deformation of the two glasses. This ensures a better control of the difference of shapes between the two glasses, which is critical for a good

product after lamination. The spatial distribution of the radiative heating power in the bending furnace is purposely nonhomogeneous, and the annular mold may also feature movable parts (Figure 11b) so as to modify the supporting conditions while sagging, in order to obtain the desired complex shape, which is not the one that a homogeneously heated glass would take upon natural sagging while supported on its periphery on simple frame.

The control of glass heating for the forming of windshield is a critical matter when, as usual, the two glasses do not have the same thickness or the same IR absorption (not the same color) or have a low-emissivity coating. Moreover, once the shape is obtained, the glasses have to be cooled down in a controlled way. As the glass at the end of the forming step is thermally nonhomogeneous, a noncontrolled cooling down would produce residual stresses as in thermal tempering. But in this case, the self-equilibrated tensile and compressive stresses would not be so much distributed across the thickness than laterally (membrane stresses). The areas undergoing the glass transition later during cooling would end up under tensile residual membrane stress. The effects could be detrimental to the gravel-impact resistance of the final windshield, as small benign cracks from the gravel impact might grow, even subcritically, under the permanent tensile residual stress. A proper control of thermal history during cooling down after forming is thus required to circumvent this issue.

At the outlet of the furnace, the two sheets of glass, now in their final shape, are separated, washed, and dried. Then a layer of PVB is inserted between them. This operation must take place in a clean room to prevent any dust from being trapped in the laminate and from becoming an optical defect in the final product. The art of manufacturing an optically clear laminated glass is essentially that of removing air bubbles in the assembly, and preventing them from coming back later upon aging. To do so, one has to remove as much air as possible from the sandwich before the final bond between the glass and the polymer is set. This is the role of a preliminary step, in which the slightly heated laminate is squeezed (for example, mechanically in between *nipper* rollers, or by processing in bags under vacuum) allowing as much entrapped air as possible to get out through the edges. The surface of the raw PVB films intended for laminate glazing fabrication may intentionally be made rough by the supplier to facilitate air evacuation. At this step, a provisional glass–PVB bond is created, but the final bond will not be given until the end of the next step, which is autoclaving. Inside the autoclave, the temperature rises up to 140 °C and the pressure up to 12–13 bars. This is enough to dissolve any remaining gaseous inclusions into the PVB and to create the final adhesion between the glass and PVB. At the end of this step, the windshield is perfectly

Figure 11 Sketch of tunnel furnace (a) and tooling (b) for windshield shaping. *Source:* From patents US 4804397 and US 5167689.

transparent and passes all the mandatory optical, mechanical, and aging tests.

4.6 Final Operations

The glazing manufacturing process ends with inspection and packaging before delivery to the car manufacturer. Prior to that step, however, there may also be some additional finishing operations: deposition of an adhesion primer on the periphery for to-be-glued parts, metallic connection soldering on the screen-printed bus bars, or apposition of different kinds of brackets for rear-view mirror or sensors. Some of these steps may take place prior to the autoclave in case of windshields. And also, as already explained, injection molding or extrusion of plastics joints or frames at the periphery, including metallic parts, is also done on demand.

5 Perspectives

Glass, as a material, has shown a remarkable ability to accompany the formidable development of the transportation industry, as particularly well exemplified by the extreme conditions that train and aircraft windshields can withstand, thanks to quite thick laminated glazing including very strong, chemically tempered glasses [28]. Glass has also successfully met tougher and tougher technological demands from car manufacturers in terms of volumes, quality, and cost efficiency, while satisfying the needs of the final customers in terms of design and functionalities.

Further progress is nonetheless desirable in various respects. Research is ongoing to modify the car glazing surface so as to make it water and smudge repellent in

a durable way under all driving circumstances. This remains a very difficult challenge. In addition, electrochromic glazing, whose light and solar heat transmission can be actively controlled, and other actively controlled privacy glazing should find their place in the car market, once their cost will be sufficiently brought down. Further acoustic comfort improvement is also needed. In the future, active noise reduction systems might somewhat open the acoustic lock on the path to more thin and lightweight car glazing. Yet another important field is the incorporation of ultra-thin, high-quality organic-light emitting diode (OLED) displays (Chapter 6.9), which will enable GPS map, rear views, or other images to be displayed in some nontransparent parts of the windshield. Likewise, opaque portions of glass sunroofs will integrate an inside lighting function, or even this function will be integrated in the transparent area, thanks to transparent OLED flat lamps. The inside face of car glazing is also expected to incorporate touch-control functions whereas transparent sensors will be integrated into the glazing: rain sensors for active control of wipers, light sensors for the active control of the optical properties of the windshield, for instance, for the provision of an automatic anti-glare function.

As electric and hybrid vehicles' share of the market increases, photovoltaic cells integrated into glazing, especially into sunroofs, allowing for electricity generation, are probably going to be more common. Additional challenges ahead are the need for curbing the CO₂ emission, and the trend toward electric vehicles and lightweighting. These are strong drivers for ever thinner glass. How is car glass going to reinvent itself to respond to these trends, while meeting safety, comfort, and cost requirements? At the same time, how is it going to integrate additional new functionalities? Innovative associations of different kinds of glasses or with other materials might be needed

for these exciting developments. But then, this will complicate further another big challenge ahead, which is recycling.

As a matter of fact, technological development is not the only reason why glass certainly has a bright future in cars. More than ever, perceived qualities, emotions, and environment consciousness are driving the car market. Glass is a perfect fit in that respect: this is a very old material that final customers have always been crediting with many qualities like purity, durability, and recyclability.

1 Introduction

With current concern over either climate or population growth, environmental protection has become a critical issue, so new technologies are rapidly emerging for energy generation and saving and, thus, reduced CO₂ emissions. Insulating materials against cold and heat play a crucial role in this respect. Among them, mineral wools, made up of silicate fibers, are most important thanks to their outstanding thermal and acoustic insulating abilities combined with non-flammability or even superior fire barrier functions. In terms of chemistry, raw materials, and production techniques, three families can be distinguished, namely, stone, glass, and slag wool, the first two being by far predominant. Depending on their functions and temperature stability ranges of service, they are used for a wide variety of applications. In all cases, however, the term *mineral* might be misleading because the fibers are not crystalline but highly vitreous as a result of hyperquenching performed at cooling rates higher than 10⁵ K/s. Hence, these glasses have higher fictive temperatures and higher potential energies than their bulk glass counterparts (Chapter 3.8).

Silicate glasses are not by themselves good thermal insulators as their thermal conductivity (K) at room temperature is typically on the order of 1 W/(m K) (Chapter 4.5). Air, in contrast, has a K value of only 0.025 W/(m K) at 283 K, which is why all efficient insulating materials rely on encapsulation of large fractions of immobile air in the form of non-connected microcells to achieve appropriately low thermal conductivities. In this respect, the fundamental advantage of mineral wools, compared with natural products, is that their fibers can be

engineered to decrease the thermal conductivity from a common 0.045 down to the very low value of 0.032 W/(m K) at 283 K for densities typically ranging from 20 to 80 kg/m³ depending on chemical composition, density, fiber diameter and orientation, and maximum temperature of use.

Stone wool has a very long history if one takes into account the so-called Pele hairs hydrodynamically drawn in air during volcanic eruptions from fluid basaltic magma (Chapter 7.2). Man-made stone wool, slag wool, and glass wool have in contrast much more recent origins since they were first produced in the 1930s as more efficient substitutes for cellulose fibers. In recent years, there has been a rapid development in mineral wool production technologies. This evolution is being driven by energy savings, fast technological developments in many relevant fields, and increases in both production capacity and market demands and also by an increasing diversity of the raw materials used. In parallel, understanding of the properties and fiber formation of mineral wool has greatly improved, which is allowing technologists to tailor the performances of insulating wools for different applications and to design and control the production processes of fibers for achieving high-quality products along with high-energy efficiency.

The production technologies and the properties of mineral wool are presented in several books [1–3] and articles [4–6], whereas there is no need to tell again the history of these processes [7]. Spinning of these materials is an enormously complicated process since it is controlled by intrinsic factors of the melt such as viscosity near the liquidus temperature, surface tension, and crystallization tendency, as well as by the extrinsic factors of the processes themselves such as spinning speed, air-jet flow rate, temperature field, external cooling condition, geometry of spinning devices, and melt-metal contact

surface. These aspects will not be discussed here. The focus will be instead on fundamental knowledge about fiber spinning processes and fiber properties of stone and glass wool, such as melt viscosity, thermal history, high temperature stability (HTS), elastic moduli, hardness, and tensile strength. Finally, attention will also be paid to high-temperature applications of these products and to the environmentally sensible issue of fiber biodegradability.

2 Classification of Man-Made Vitreous Wool

All types of commercially important man-made vitreous wool are silica based, i.e. they contain $[\text{SiO}_4]$ units as network formers along with various amounts of oxides of boron, aluminum, alkaline earths, alkalis, iron, and zirconium, which are added to enhance the manufacturing process or the product performance. The general classification of man-made vitreous wool includes two subsets: mineral and refractory ceramic wool (Figure 1). Stone wool is usually prepared from raw materials such as recycled materials, volcanic rock (typically basalt), and the olivine $[(\text{Fe,Mg})\text{SiO}_4]$ and dolomite $[\text{CaMg}(\text{CO}_3)_2]$ minerals, whereas slag wool is synthesized primarily from blast-furnace slag ([1], Chapter 7.3) and glass wool from sand, recycled glass, limestone, soda ash, and other chemical additives (Chapter 1.2).

The chemical compositions of four typical examples of man-made vitreous wools are listed in Table 1, where the presence of low- and high-alumina products is to be noted for stone wool. The chemical compositions of both glass and slag wool are also displayed in Table 1. Despite being termed *slag wool*, this wool is also highly glassy since it is hyperquenched during fiber formation.

Man-made vitreous wool fibers are manufactured with a variety of processes based on the attenuation of a thin stream of molten inorganic oxides at high temperatures. Depending on the process, they are produced as discontinuous fibers of variable lengths and diameters that are intimately tangled. This feature distinguishes *wools* from

Table 1 Examples of mineral wool compositions (wt %).

Oxide	Stone wool		Glass wool	Slag wool
	High Al_2O_3	Low Al_2O_3		
SiO_2	36–42	50–52	60–70	33–42
Al_2O_3	17–24	>3	3–7	11–20

B_2O_3	0	0	3–7	0

fibers (cf. Chapter 1.6), the latter being continuous or discontinuous.

3 Fiber Spinning Technologies

Two main spinning technologies are used for the production of vitreous wool fibers. Stone and slag wool fibers are traditionally produced with a cascade spinning process (i.e. external centrifugation), whereas glass wool is produced by rotary spinning (i.e. internal centrifugation). Besides, other fiberizing processes such as flame attenuation and air blowing are mainly used for production of high-temperature insulation wool and thin insulation wool fibers.

With the exception of those used in high-temperature applications, the newly drawn fibers are immediately coated with an organic-binder spray before being collected on a conveyor belt as a continuous blanket. When it has reached a given thickness, the blanket enters a curing chamber for binder polymerization and is finally cut into the requested specific dimensions and compressed to some extent to reduce the volume of the product as much as possible for transportation and storage before use.

The main function of the binder is to hold the fibers together. It is often a phenol-based resin that typically can account for up to 1–10% of the mass of the final product. But alternative binders such as acrylic binders or binders based on sugar are being introduced because of increased concern on chemicals such as formaldehyde, which is a component of the phenol resin.

3.1 Cascade Spinning Process

The principle of the cascade spinning process is sketched in Figure 2a. The starting melt for the fiber is produced in a coke-fired cupola or in an electric- or gas-heated furnace with capacities of approximately 100–400 ton/day. Depending on capacity, each melting unit has from one to three spinners, which consist of up to four water-cooled alloy wheels (circumference: approximately 0.5–1 m) with parallel axes rotating at a speed of 5000–8000 rpm. At a temperature of approximately 1400 °C, the melt with a very low viscosity of about 2 Pa·s is imposed onto the rotating spinning wheel. This transfer causes a sharp temperature drop and, correlatively, a viscosity increase [3, 4]. While some fibers are spun off by the centrifugal force from bulge-shaped instabilities at the wheel-melt layer, the rest of the melt falls on the next wheel for fiber spinning.

Upon wheel rotation, bulge-shaped instabilities occur on the surface of the melt film, which are caused by a combination of the high acceleration field of the wheel and an air jet. The bulges remain connected with the melt

film via surface tension and viscous forces [4], but they are eventually torn off to give rise to a melt droplet. It is the narrow melt ligament connecting a droplet to its bulge that is stretched as a fiber under the centrifugal force of the wheel. The fiber breaks when the stretching stress exceeds its tensile strength, which happens for a mean diameter of 2–5 μm and a mean length of up to 5 mm, while the remaining droplet is frozen in as a *shot*. Because shots account for 25–40 wt % of the raw stone wool, they are for the most part separated from the wool by gravity right after fiber spinning to be melted and fiberized again, the rest being left in the wool.

The properties of final products are determined by numerous factors, which include the wool packing structure, binder distribution in the product, fiber diameter and length, fiber spatial distribution, and shot fraction. Because the efficiency of fiber spinning depends on viscosity and melt homogeneity, melting in the melting units must be performed at a high temperature of about 1500 °C for at least half an hour. In addition, it is essential to maintain a stable melt flow to the spinner and to control properly the impingement point of the melt flow on the first spinning wheel to optimize spinning and improve wool quality by reducing in particular the shot fraction. In this respect, the air-jet rate around the spinner wheels is an important feature influencing shot formation [4].

Reducing the shot fraction of the raw wool actually is a crucial point to increase the efficiency of the process. For this purpose, experiments and numerical modeling have

Figure 2 Sketch of the two main techniques for forming mineral wool. (a) Cascade spinning process; diameter of a spinning wheel: about 160–320 mm. (b) Rotary spinning process (different design for the disk and the fiberizer in the TEL process); diameter of a spinning disk: 300–600 mm.

investigated the relation between shot formation and the initial instability of the melt film on the spinner wheel. The main source of this instability lies in the centrifugal force accelerating the light air toward the denser melt. Finite-element simulations have shown that the size and shape of droplets strongly depend on the size of the initial instability of melt films as described in [3]. The droplet size decreases when the size of the instability is reduced through an increase of the melt temperature. Increasing the rotation speed of the wheel (i.e. increasing the spinning speed) also makes drops smaller, thereby decreasing the shot fraction of the wool product and making at the same time fibers thinner. Furthermore, the shape of melt droplets is influenced by the initial instability domains. In general, it becomes more roundish with increases of melt temperature and surface tension, whereas the droplet front parts get less roundish (or more square shaped) with an increase of the wheel rotation speed. These effects must thus be balanced to optimize both production efficiency and wool performance.

3.2 Rotary Spinning Process

Although stone wools with specially designed compositions can also be fiberized with it, the rotary spinning process is commonly used for the production of glass wool. One of the designs is sketched in Figure 2b. Another is the Saint-Gobain TEL process, which differs regarding the design of both the spinning disk and the fiberizer. In both cases the required high-quality melt is produced in gas-recuperative or oxyfuel furnaces whose capacity ranges from 10 to 200 tons/day for a single line with up to six spinners. As in the cascade process, fibers are spun by a combination of centrifugal force and gas blowing. The former is produced by a spinning disk 300–600 mm in diameter rotating at 2 000–3 000 rpm whose sidewall is perforated with 30 000–50 000 holes ~1 mm in diameter uniformly distributed around the circumference. Disks are made of Fe-, Ni-, or Co-based superalloys (Chapter 5.10), which must not only have outstanding mechanical properties to sustain high rotation stresses at elevated temperatures but also resist glass corrosion and oxidation by the surrounding air. As a matter of fact, such superalloys had to be specially developed for these applications.

When a melt stream falls at a controlled rate into the disk, it is extruded as melt jets through the holes by an outwardly radial centrifugal force. Because melt jets grow and move under the combined effect of viscosity, surface tension, gravity, and aerodynamic forces [5], they are forced into the fiber spinning zone where they are attenuated by a suitable blowing flow. The speed and temperature of the gas flow depend on the design of the fiberizer. There are two different gas flows, which interact with

the arising fiber curtain. One is directed downward at 1500 °C to keep the jets warm and highly deformable near the nozzles. At a temperature of about 30 °C, the other is a highly turbulent cross-stream airflow, which stretches and quenches the hot jets as solid fibers and then pushes them down to a conveyor belt below the spinner. The fibers have a mean diameter of 2–6 μm and a mean length of 2–6 mm. As for the fraction of unfiberized particles, it is lower than 1% because all melt goes through the extrusion stage in the spinning disk.

As evidenced in many experimental studies, the efficiency of the rotary spinning process strongly depends on melt temperature, viscosity, rotational speed of the spinner disk, number and size of the holes in the spinner disk, and the surrounding temperature of the airflows. In general, the process must be conducted at viscosities of 50–200 Pa·s at which melt temperatures range from 950 to 1100 °C. Owing to the complexity of the fiber spinning mechanism, numerical simulations have been conducted to provide insights into the fiber formation. An asymptotic coupling concept was introduced for fluid–fiber interactions [5]. The melt jets cause the airflow to swirl, whereas the fiber jets deflect the burner flow. The resulting axial flow velocity and temperature profiles determine the fiber spinning momentum and the heat exchange, respectively. The temperature of the fiber jets depends on the arrangement of the spinning rows, i.e. on the distance between the burner and the rows of the spinning holes in the disk [5]. Because the jets from the highest rows are warmer than those from the lowest, they have a faster fiber stretching ability and hence yield thinner fibers. But the wool quality requires a narrow diameter distribution of fibers, and therefore nozzle geometry, nozzle diameters, and distances between spinning rows in the disks must be optimized to reduce temperature gradients in the spinning disk. Again, numerical simulations are useful in this respect to model the interactions between the melting and spinning domains and to optimize the process regarding energy consumption and robustness [5].

4 Melt Viscosity and Fiber Spinnability

Spinnability is the ability or suitability of a glass-forming melt to be stretched or spun into defect-free fiber filaments. It first depends on intrinsic factors, of which the most important is the temperature dependence of the melt viscosity (Chapter 4.1). At the same T_g/T (Figure 3), the viscosity is, for instance, lower for stone than for glass wool compositions. This difference has important consequences because higher fiber spinning temperatures are required for the former than for the

Figure 3 Viscosity–temperature relationships of stone and glass wool melts in a fragility plot where the glass transition temperature (T_g) was measured by differential scanning calorimetry. Liquidus temperature (T_{liq}) also determined by DSC (cf. Figure 4), but not indicated for the glass wool for lack of crystallization signal in DSC thermograms. Solid lines: fits of Eq. (2) to the viscosity data.

P ₂ O ₅	0.3	<0.1		

The wool and continuous fibers with basalt and E-glass compositions were made as model samples [8–10].

latter to obtain similar melt homogeneity, fiber geometry, and wool yields.

For typical stone and glass wool compositions (Table 2), the viscosity is well described by a three-parameter equation [11]:

$$\log \eta = \log \eta_{\infty} + \frac{B}{T} \exp \left(\frac{C}{T} \right), \quad (1)$$

where η_{∞} is the high-temperature limit of viscosity and B and C are constants. Compared with the Vogel–Fulcher–Tammann (VFT) equation, Eq. (1) benefits from a stronger physical foundation that ensures accurate predictions of low-temperature viscosities without any

singularity at finite temperatures [11]. For convenience, it can be expressed in terms of the liquid fragility index (m) and glass transition temperature (T_g) [11]:

$$\log \eta(T) = \log \eta_{\infty} + (12 - \log \eta_{\infty}) \frac{T_g}{T} \exp \left[\left(\frac{m}{12 - \log \eta_{\infty}} - 1 \right) \left(\frac{T_g}{T} - 1 \right) \right], \quad (2)$$

where both m and T_g are obtained from fits of Eq. (2) to the relevant viscosity data. The values of m determined in this way are 46 and 50 for the stone and glass wool compositions, respectively, indicating that the former is more fragile than the latter and thus is slightly less vitrifiable. This conclusion is borne out of the stronger crystallization tendency of stone compared with glass wool compositions as revealed by an intense exothermic peak in a differential scanning calorimetry (DSC) thermogram (Figure 4), which is observed for the former and is lacking for the latter.

Although high glass-forming ability usually translates into high fiber spinnability, the viscosity at the spinning temperature must also be considered because it must be higher than a critical value (η_c) below which too low cohesive forces would prevent the melt from being stretched. Since η_c depends on the structural relaxation time of the melt, it increases with the timescale of the process. For rather slow continuous fiber drawing (via the bushing technique), it should be in the 30–200 Pa·s range, with an empirically favored value of about 100 Pa·s, whereas it may be as low as 1 and 50 Pa·s for the cascade and rotary processes, respectively. In this respect, some flexibility results from the fact that the spinning temperature may be slightly lower than the liquidus as long as crystal nucleation and growth remain relatively slow

Figure 4 Phase transformations of a stone wool composition as observed in a DSC thermogram for a sample heated under argon at a rate of 20 K/min. T_g : glass transition temperature. T_c and T_{end} : onset and offset temperatures of crystallization. T_{mc} and T_{liq} : onset and offset temperatures of melting.

phenomena (Chapter 5.4). In this case, they do not produce solid inclusions in the flowing melt large enough to hamper the process during the very brief time lapse of spinning.

As a matter of fact, the ratio between the viscosity at the liquidus, η_{liq} , and η_c may be used to characterize the intrinsic fiber spinnability, which is best for the highest values of this parameter as long as specific effects of surface tension can be neglected. This is actually the case for most of the mineral wool fiber-forming melts because differences in surface tension at T_{liq} are much smaller than in viscosity. That η_{liq} is the dominant parameter determining the intrinsic fiber spinnability does not mean, however, that other factors such as surface tension should not be taken into account when designing the fiber spinning process and facilities. And, of course, extrinsic factors must also be considered. As already stated, the spinning speed, centrifugal force, external cooling rate, temperature of the spinning wheel, etc. must all be optimized to obtain an elevated output of high-quality products and achieve enhanced energy efficiency. But further discussion of these engineering factors is beyond the scope of this chapter. A detailed definition and quantification of fiber spinnability are reported in [6].

5 Physical Properties of Stone and Glass Wool

5.1 Thermal and Mechanical Histories

Among glass products, mineral fibers distinguish themselves by the fact that they do not need to be annealed because of a lack of temperature gradient and hence of internal stress resulting from their very small diameters [3]. They are hyperquenched and thus still farther from equilibrium than their bulk counterparts. In addition, the fibers keep a memory of the drawing stresses to which they were subjected during spinning. Hence, the structural atomic disorder and associated potential energy of the fibers reflect the specificities of this thermal and mechanical history with the consequence that the physical properties of these materials differ considerably from those of their bulk counterparts. A simple calculation of the actual cooling rate of mineral wools will illustrate this statement simply.

In a first approximation, the thermal history of a glass can be characterized by its fictive temperature (T_f), i.e. the temperature at which the liquid structure has been frozen in, which may itself slightly depend on the particular property considered. Here, T_f is calculated for the stone and glass wool samples (Figure 5) with an enthalpy-matching approach [12] from the temperature dependence of the isobaric heat capacity (C_p). For this purpose, measurements have been made on heating at 20 K/min

Figure 5 Enthalpy relaxation of stone and glass wool samples determined in DSC measurements of the heat capacity made at a heating rate of 20 K/min through the glass transition range. C_{p1} : measurements on the as-produced sample. C_{p2} : second upscan made right after the first.

first on as-spun fibers (C_{p1} in Figure 5) and then on the same sample cooled down at 20 K/min (C_{p2}), which are in this way annealed as usual. In Figure 5 the areas enclosed by the C_{p1} and C_{p2} curves thus represent the total enthalpy trapped in the fibers by hyperquenching, which are calculated to be 64 and 44 J/g for stone and glass wool, respectively. According to [12], fictive temperatures of 1150 and 975 K are derived from these values for the stone and glass wool samples, respectively, which are 19 and 17 % higher than their standard glass transition temperatures of 960 and 831 K. From the viscosity at T_f , the cooling rate q_c of the fibers can be determined with the relation [12]

$$\log q_c = 11.35 - \log h(T_f). \quad (3)$$

From the viscosity data (Figure 3), one then finds that the cooling rates of the stone and glass wool fibers are distinct at about 10^6 and 10^5 K/s, respectively, even though their parent melts exhibit similar T_f/T_g ratios. The reason for this contrast is that, in fiber spinning windows, the glass wool melt is about ten times more viscous than the stone wool melt at their respective fictive temperatures. In other words, cooling rates must indeed be ten times higher for the cascade spinning process than for the rotatory spinning process to obtain the similar T_f/T_g ratios actually borne out in practice.

5.2 High Temperature Stability

Although fiber crystallization is to be strictly limited during production, this process confers outstanding mechanical properties to mineral wools in fire-protection applications when heated fibers keep upon partial crystallization their shapes up to temperatures of 1300 K or

more. Depending upon the nature of the surrounding atmosphere, the HTS is thus defined as this ability of wool fibers to keep their original geometric shape at high temperatures. For readily vitrifiable glass wools, this ability is virtually nonexistent because crystal nucleation and growth take place at temperatures at which the super-cooled liquid has already sintered as a dense bulk glass that has thus become useless as an insulating material.

As already noted, stone wool fibers in contrast crystallize more readily (Figure 4). Upon dynamic heating at 20 K/min under an argon atmosphere, the augite pyroxene $[(\text{Si,Al})_2\text{O}_6](\text{Ca,Mg,Fe,Ti,Al})_2$ and albite feldspar $[\text{NaAl-Si}_3\text{O}_8]$ precipitate between onset (T_c) and offset (T_{end}) temperatures of about 1125 and 1240 K before melting begins at a temperature T_{mc} of about 1300 K. In this case, however, the HTS is not that high because crystallization does not prevent the fibers from collapsing from about 1100 K.

A higher HTS of about 1350 K is in fact achieved in air thanks to the oxidation of ferrous into ferric iron by an internal redox reaction (Chapter 5.6) whereby Ca^{2+} , Fe^{3+} , and especially Mg^{2+} ions diffuse from the interior toward the surface of the fiber. There, they react with oxygen to form at the fiber surface, mainly periclase $[\text{MgO}]$ as a nanocrystalline layer whose thickness increases linearly with increasing degree of oxidation and can reach about 100 nm for complete oxidation of the ~ 7 wt % FeO content of the material [13]. Although the melt viscosity somewhat increases correlatively upon oxidation, the major effect on the HTS results from the presence of this periclase layer that not only markedly hinders sintering but also allows the softening fibers to keep their shape thanks to the mechanical support they provide. Eventually fiber collapse nonetheless takes place near 1350 K at the onset of melting and of disappearance of the nanocrystalline layer and the interior crystals [13].

5.3 Elastic Modulus and Hardness

The intrinsic elastic and plastic responses of a fiber subjected to an external mechanical load are critical features in any use of insulating wool. They depend on the thermal and mechanical history of the material and, therefore, on the fiber spinning conditions. The relevant parameters in this respect are the reduced elastic modulus (E_r) and hardness (H), which can both be measured with a specifically designed nano-indentation technique [8]. In practice, E_r is defined by the load–depth unloading stiffness S through the relation $E_r = 0.5S\sqrt{\pi/A_C}$, where A_C is the projected contact area at the maximum depth of penetration, S is obtained from the unloading curve slope, and H is defined as P_{max}/A_C , where P_{max} is the maximum load used for indentation. Because these properties also

Figure 6 Effect of fiber diameter (as d^{-1}) on mechanical properties of three types of wool fibers as determined with a nano-indentation technique under a load of 1000 μN [8]. (a) Atomic force microscope micrograph of an indent on the surface of the stone wool fiber with a diameter of about 6 μm . (b) Reduced elastic modulus (E_r). (c) Hardness (H).

vary with chemical composition, we summarize in Table 2 the results obtained for stone, basalt, and E-glass wools, the last one – also prepared with the cascade spinning process – serving as a reference for the two others.

Actually, the most important parameter to be investigated is the fiber diameter d , which itself increases with decreasing cooling rate and fictive temperature. When plotting E_r and H against the reciprocal of d , so as to include bulk glass properties, one observes that both increase with it (Figure 6). The reason is of course that

glasses with a higher T_f have more open structures and, hence, a lower resistance to elastic and plastic deformation and densification. Interestingly, these variations for a given glass are larger than the differences between the three glasses for a given diameter, E-glass having the highest moduli (as expected from its use in reinforcement; cf. Chapter 1.5).

5.4 Tensile Strength

Even though much work has been done on fiber fracture, the process is not well enough understood yet because it depends on a combination of factors such as chemical composition, melt homogeneity, thermal and mechanical histories, fiber shape and size, and surrounding atmosphere. Here we will limit ourselves to the relationship between the tensile strength and the axial stress exerted upon fiber drawing for the basalt sample of Table 2, taking again as a reference E-glass continuous fibers spun through the nozzle of a 90Pt/10Rh (wt %) crucible. For all samples the tensile strength was measured at room temperature for a relative humidity of 80% [9]. For both glasses, the tensile strength first increases very strongly up to a σ_{ax} of about 10 MPa and then reaches a plateau at about 3100 MPa for E-glass (Figure 7a) and ~3500 MPa for basalt (Figure 7b). Since wool fibers are stretched at a lower axial stress (caused by centrifugal force) than continuous fibers, but at a higher stress than the bulk glass, the fiber drawing force appears to be a key factor to determine the fiber strength.

Because the structural anisotropy of the fibers linearly increases with σ_{ax} [10], the orientation of structural units along the fiber axis initially plays a positive role in enhancing tensile strength. Upon fiber spinning, the defects also become stretched and oriented along the fiber axis at much smaller shear stress or axial stretching than structural units. Like oriented species or structural units present in other materials, they should then reduce the probability of catastrophic fracture. However, the existence of a plateau above a certain σ_{ax} suggests that other factors then come into play and start to cancel out the

positive effect of the structural orientation on the fiber strength. Defects such as microbubbles, seeds, striae, and structural heterogeneities are inevitably present and represent potential sources of fracture (Chapter 3.11). In other words, the tensile strength of fibers will no longer be enhanced just by increases of the structural anisotropy.

Of particular interest is finally the large excess of tensile strength of the wool fibers (1500 MPa) over the bulk glass (80–200 MPa) indicated as Interval 2 in Figure 7. This excess likely originates in two major effects: (i) a lower probability for the presence of surface flaws on fibers compared with bulk glasses and (ii) the lack of oriented features in bulk glasses.

6 Biopersistence and Biodurability

Owing to the morphological similarity between mineral wool and asbestos, much work has been done to determine whether mineral wool could be cleared by the lung physiological mechanisms, through dissolutions, breakage, phagocytosis and mechanical removal via the mucociliary escalator. Experimentally *biopersistence* is investigated *in vivo*, whereas *biodurability* or dissolution rates refer to *in vitro* measures of dissolution [14, 15], which reflect the chemical degradation (dissolution) of the fibers but not the physical clearance.

As a first step, specific *in vitro* tests have been performed to determine the dissolution rate of the mineral wool fibers as a function of chemical composition in an environment mimicking that of the lung. Appropriate conditions are met with a medium similar either to the near-neutral (pH 7.4) extracellular lung fluid or to the acidic (pH 4.5) regime defined by the phagolysosomes of the macrophages present in the lung. In addition to being dissolved, the fibers can also be removed mechanically from the lung via macrophage clearance.

An important feature is that dissolution in the lung is more rapid for mineral wool than for crystalline fibers because the former, with its long-range disordered

Figure 7 Increases of tensile strength σ_{ts} with the axial drawing stress of fibers (σ_{ax}) (replotted from [9]). (a) E-glass fibers. (b) Basalt fibers. Interval 1: σ_{ts} difference between continuous and wool fibers for similar diameters. Interval 2: σ_{ts} difference between wool fibers and bulk glass of the same compositions.

structure, is metastable relative to the latter and thus has a larger thermodynamic driving force (i.e. larger decrease in Gibbs free energy) for dissolution. As the dissolution rate depends on glass composition, numerous *in vitro* studies have been carried out with the dual purpose of predicting this dependence in terms of the different structural units of the glass network and the simulated lung fluid and of correlating the results with *in vivo* biosolubility. For high-alumina low-silica glasses (i.e. with >7 wt % Al_2O_3 and <43 wt % SiO_2), the *in vitro* dissolution rate at pH 4.5 correlates with the *in vivo* biosolubility [16], whereas for low-alumina glasses (i.e. with <5 wt % Al_2O_3), the *in vitro* dissolution rate at pH 7.4 correlates with the *in vivo* biosolubility [17]. Thus, the dissolution rate indeed reflects *in vivo* biosolubility.

In most cases, a mineral wool fiber composition with a higher dissolution rate at pH 7.4 shows a lower dissolution rate at pH 4.5 and vice versa [18]. Alumina has indeed a strong but complex effect on the *in vitro* dissolution rate (Figure 8). At pH 7.4, the dissolution rates of both stone and glass wool fibers drastically decrease with increasing alumina content up to ~5 wt %, i.e. up to a $Al^{3+}/(Al^{3+} + Si^{4+})$ ratio of ~0.07 (Figure 8a). Above 5 wt % alumina, the dissolution rate only slightly increases. In contrast, at pH 4.5 (Figure 8b), the dissolution rate of stone wool fibers remains almost unchanged with $Al^{3+}/(Al^{3+} + Si^{4+})$ ratio up to about 0.25, and then increases linearly. Based on these findings, low-biopersistent stone wool fibers have been developed along two different

routes. One is to adjust the alumina content to a level above 14–16 wt % and the silica content to below 42–43 wt %, whereas the other is to lower the alumina content to below 3–4 wt %. Both types of fibers have demonstrated high biosolubility according to *in vivo* tests. In addition, the absence of relevant pathogenicity and a lack of anomalous neoplastic changes have been observed in long-term inhalation tests on these fibers.

7 Perspectives

In today's complex markets, a single insulating material cannot satisfy all possible requirements. Silica aerogels have, for instance, record low thermal conductivities, but their high cost restricts them to niche applications (Chapter 8.3). Polyurethane foams are the main other products having a lower thermal conductivity [of about 0.028 W/(m·K)] than mineral wool, with the advantage of good mechanical properties but the disadvantage of flammability. Although improvements in physical performances and development of new compositions with low biopersistence have been made in the past two decades, a potential remains to develop even better products along with more efficient fiber spinning processes. A better understanding of the relations among chemical composition, fictive temperature, viscosity, and cooling rate is, for instance, critical for optimizing both cascade and rotary fiber spinning processes with respect to fiber output and quality. Likewise, a physically based value for the highest fiber spinning efficiency still needs to be found through numerical modeling and molecular dynamics simulations in combination with experimental studies.

Glasses for Solar-energy Technologies

Joachim Deubener and Gundula Hensch

Institute of Non-Metallic Materials, Clausthal University of Technology, Clausthal-Zellerfeld, Germany

1 Introduction

According to the International Energy Agency (IEA), the worldwide energy consumption was 574×10^{18} J in 2014, of which only 0.24% was solar in origin in the form of electricity or heat. By comparison, sunlight brings about 4×10^{24} J/yr to the Earth (annual solar energy = average sun irradiance at ground level [1050 W/m^2] times the Earth's surface exposed to the sun [$(4/\pi) \times 10^{14} \text{ m}^2$] times seconds in a year [3.1×10^7]). Even if one considers that the ocean and other uninhabitable areas represents 90% of the Earth's surface, the energy directly harnessed from sunlight represents less than 10 ppm of the amount received in inhabited areas. The motivation for increasing significantly this fraction is thus clear, especially as one may in addition expect an improved energy security, less pollution, a lesser human footprint, or even more stable prices for fossil resources.

In this respect, the basic point is that all types of solar conversion systems rely on glass, to such an extent that for some them this material is simply without any alternative [1, 2]. The combination of transparency, chemical inertness, strength, rigidity, and high-temperature stability is in effect unique to glass. Additional advantages are almost limitless shapability, which makes production of versatile geometries such as tubes and panes at large scale possible, as well as surface tailoring by physical or chemical means. Besides, glass is an environmentally friendly material as it is not only free of carcinogenic, mutagenic, and reprotoxic substances but also 100% recyclable (Chapter 9.9). Sustainability over its entire life cycle thus manifests itself in a cradle-to-cradle certification of most glass products for solar applications.

After a sketchy review of the energy problem, this chapter will thus describe the various uses of glass in the variety of solar-energy devices currently in use or still under study. Photovoltaic (PV) cells will be first considered, followed by solar heating devices, solar thermal-power plants, natural and artificial photosynthesis processes, chemical water splitting, and finally desalination and disinfection setups.

2 The Energy Problem

The International Energy Outlook 2016 released by the U.S. Energy Information Administration forecasts that the worldwide marketed energy consumption will rise by 39% between 2016 and 2040. The strongest growth is expected for countries not belonging to the Organisation for Economic Co-operation and Development (OECD), particularly in Asia. Fossil fuels (oil, coal, and natural gas) have the largest share (82%) on the world's energy consumption today and are predicted to account for 78% of global energy used in 2040. Ever since the Industrial revolution, the atmospheric concentration of carbon dioxide has increased steadily at an annual rate of about 0.5% in 2015 (see, for instance, the observations begun in 1958 at the Mauna Loa Observatory in Hawaii known as the *Keeling curve*, released daily by the Scripps Institution of Oceanography at UC San Diego). Because 90% of human CO₂ emissions result from the combustion of fossil fuels for electricity, heat, and transport, future energy use has emerged at the center of the current climate debate. Deep cuts in CO₂ production have in particular been called in countries such as China and the United States, which are by far the biggest world emitters.

Besides a general reduction of energy consumption, the supply of primary energy from carbon-neutral sources has become one of the society's most important

Reviewers: R. Conradt, RWTH Aachen University, Aachen, Germany
L. Wondraczek, University of Jena, Jena, Germany

challenges. Hence, most industrialized countries have established fiscal incentives and legal instruments such as the pioneering *Renewable Energy Sources Act* in Germany to decrease the initial market entry barriers of solar-energy systems and to reduce the costs for production and consumption over a period of time.

Glass contributes to the primary energy demand to produce materials incorporated in solar energy conversion devices and to a lesser extent of about 13% for single-crystal and thin-film PV modules, respectively. Because the payback times for today's solar technology systems are substantially shorter than their expected lifetimes, increasing the use of glass in such devices remains relevant in terms of sustainability and carbon footprint. With an energy expense of 2500–2800 kWh, about 450–500 kg of CO₂ are emitted when 1000 kg of glass are melted to make about 130 m² of 3 mm-thick glass panes, not counting the other 160–180 kg resulting from the decomposition of soda ash, limestone, or dolomite (Chapter 1.3).

3 Solar Electricity

3.1 First- and Second-generation Cells

PV cells are designed to convert directly solar energy into electricity. Two generations of cells are currently produced (Figure 1). The first is still having a very large market share of 90% in 2015 with wafers made up of either single-crystal (sc-Si) or polycrystalline (pc-Si) silicon [3–5]. Most such modules have a single sheet of glass as front material and a non-glass back cover. Glass is also found in electrode materials to ensure efficient contact with the silicon. For building integrated concepts, square cells are laminated between two glass plates.

The second generation PV cells rely on thin-film technologies based on cadmium telluride (CdTe), copper indium (gallium) diselenide (CIS/CIGS), and amorphous and microcrystalline silicon (a-Si/ μ -Si) semiconductors. In this case one builds the cell by depositing transparent

Figure 1 Low-iron glasses in photovoltaic cells. Left: first-generation Si modules with a figured rolled glass cover (a), an AR-coated float glass cover (b), or two float glass panes for building integration (c). Right: second-generation thin-film modules, with AR-coated float glass as a generic superstrate (d), textured and non-textured TCO and back-contact layers (e), and float glass coated with an Na-blocking layer serving as a substrate for CIGS cells covered by a second float glass pane with an AR-coating (f).

electrodes and semiconductor layers onto a sheet of glass in two different configurations, namely *superstrate* (sunlight illumination through this glass sheet) or *substrate* (a nontransparent material can also be used as substrate). A back glass sheet is laminated to the superstrate to encapsulate the device or a non-glass back cover is used. For substrate configurations, a glass plate is laminated as front cover.

3.2 Front and Back Glasses for PV Modules

The front glass ensures the mechanical robustness of the entire PV module, hermetically protects the cell from the environment, and maintains the high transparency of the semiconductor layer. The front is usually made of soda-lime-silicate glass whose relatively high coefficient of thermal expansion (CTE) of 8–9 ppm/K is not problematic in view of the lack of important thermal stresses experienced. The glass is thus made with either the float or rolled-plate process (Chapter 1.4) with a thickness that is commonly 3.2 mm but can range from 2 to 4 mm depending on the module type. The front glass contributes to two third of the module weight (crystalline silicon) but this fraction can increase to more than 90% for thin-film cells with both glassy front and back.

Rolled-plate glass has a structured surface that makes lamination easier, provides a non-blinding effect (no hazard to air navigation), and nicer aesthetics. Plates can also be figured if the rolls carry a pattern. A high-relief pattern such as diamonds is then impressed in the soft glass to increase light trapping, whereas a burred surface structure is often used to enhance the adhesive strength between the glass plate and the encapsulant material, which is most commonly ethyl vinyl acetate $[(C_4H_6O_2-C_2H_4)_n]$ (Chapter 8.8). This material provides mechanical support, optical coupling, electrical isolation, and environmental protection of the PV cell. With currently more than 80% of the market share, rolled-plate glass is increasingly used for both sc- and pc-Si cells.

For second-generation thin-film cells, the float industry offers various types of coated glasses meeting the specific requirements of the different modules, thanks to the extremely plane and smooth surfaces obtained on both sides (root-mean-squared roughness $R_a < 0.5$ nm). For CIS/CIGS cells, a SiO_2 passivation layer is applied directly on the glass surface to prevent migration of sodium from the glass into the cell structure before coating with transparent conductive oxides (TCO), whereas molybdenum is first coated on the back glass. For a-Si/ μ -Si cells, the TCO material itself is deposited in a textured form to trap photons by internal reflection in both TCO conductivity (sheet resistance) and light trapping (haze).

Both float and rolled front glasses are thermally strengthened by airflow quenching after heating at about

620–650 °C (Chapter 3.12) to improve glass strength by a factor of about 4, with a flexural strength in the range 120–200 MPa depending on thickness, edgework, etc. Front glasses are also coated with a broad-band antireflective (AR) layer to minimize reflective losses at the surface of the solar module. Although different types of reflection-controlling layers are commercialized, a single coat of a sol-gel-derived nanoporous silica (Chapter 8.2) has become the golden standard with more than 90% market shares, thanks to its cost efficiency, mechanical stability, and bandwidth.

The coating relies on the formation of an effective optical material of low refractive index. According to Fresnel's law, under normal incidence the refractive index of the AR-coating should be the root square of that the front glass, i.e. $n_{\text{coating}} = 1.23$ for a soda-lime-silicate glass ($n_{\text{glass}} = 1.52$). Depending on the mixing model selected (Lorentz–Lorenz or Drude), a porosity of 47–55% is needed to achieve such a low refractive index from coexisting silica ($n_{\text{glass}} = 1.46$) and air ($n = 1$). Deposits are made a quarter-lambda thick to ensure the optimum in the destructive interference between the sunlight reflected at the air/AR-coating surface and AR-coating/glass interface, that is $\lambda/4n_{\text{coating}} \approx 110$ nm for the peak intensity wavelength ($\lambda = 500$ nm) of the solar radiation.

In the majority of processes, the final porosity and adherence with the front glass is achieved during the heat treatment made for thermal strengthening. Sodium migration from the bulk glass into the AR-coated interface is then beneficial to ensure the high mechanical stability of the coating. One can make the deposition by rolling or spraying an aqueous dispersion of silica colloids on one side of the front glass plates or by dipping the glass sheet into the coating solution and withdrawing it with a constant speed [6]. An alternative is spraying of an aqueous potassium-silicate solution, which then dries into a gel of interconnected silica colloids and dispersed potassium hydroxides and carbonates [7]. To achieve nanopores between silica particles, the latter materials have to be washed away in a subsequent cleaning step. In addition, subwavelength periodic or stochastic surface-relief structures are designed to reduce efficiently reflective losses [8]. An AR-coating can consist of a larger fraction of open porosity that leads to capillary condensation and stronger surface alteration under long-term environmental exposure. The degree of open porosity depends on the type of silica colloids (hollow versus dense particles) and their connectivity (grading) after thermal consolidation.

The use of low-iron content glass is intended to reduce the absorption of sunlight by the front glass sheet itself [9]. Soda-lime-silicate glasses are thus made from high-grade sand, which cuts the total iron content to below 0.014 wt % Fe_2O_3 (=100 ppm w/w Fe). Ferric iron absorbs sunlight from the ultraviolet (UV) region by the low-

frequency tail of a strong charge-transfer band around 220 nm and by intramolecular d–d electron transitions at 385, 420, and 435 nm (molar extinction coefficient up to 4.8 l/mol/cm), whereas ferrous iron has a broad absorption band centered around 1060 nm in the near infrared (NIR) part of the solar spectrum (molar extinction coefficient 54 l/mol/cm) (Figure 2, see also Chapter 6.2). As a result of reducing conditions created by sulfur fining and carbon additions, the absorption bands of Fe^{2+} are usually the most intense. Oxidizing agents like cerium oxide are thus added to the batch to increase its $\text{Fe}^{3+}/\text{Fe}^{2+}$ ratio, others (e.g. antimony oxide) being avoided for environmental reasons. But a negative side effect then is the formation of photoinduced electron and positive hole centers upon prolonged and intense sunlight, which causes glass discoloration by shifting the UV edge into the visible frequency range. To overcome this *solarisation* problem and, thus, make radiation-stable glasses, a mix of different oxides for the redox control of polyvalent iron is used in practice.

The achievable transmittance τ of the front glass in the PV-relevant range of wavelengths can be derived from conservation of energy as $\tau = 1 - (\alpha + \rho)$ where α and ρ

are losses due to absorption and reflection of light in the volume and at the surfaces of the glass sheet, respectively. According to Beer–Lambert law, the attenuation of light depends on both the concentration of the absorbing species and thickness of the glass plate. Thus, a thinner front glass plate reduces not only the weight of the module but decreases also absorption losses. In the range 300–1100 nm the peak transmittance of a 4 mm-thick low-iron float glass at normal incidence is 91.3% (Figure 2). The reduction of the thickness to 3 mm results in a gain of about 0.2%. A figured low-iron rolled glass can reach a slightly higher value but shows a stronger gain if larger angles of incidence are considered. Another gain of peak transmittance of about 4% on both floated and rolled glass is obtained with a single-side AR-coated low-iron solar glass.

N.B. In photovoltaics, normalization of the transmittance is usually done in terms of the photon flux of the sun, which is the number of photons per area per time ($\text{m}^{-2} \text{s}^{-1}$). To convert the energy flux of the reference spectra (AM1.5g) in a photon flux, the spectral irradiance thus has to be divided by the photon energy $= hc/\lambda$ (h = Planck constant, c = speed of light). With a photon

Figure 2 Spectral transmittance and loss of photon flux of different float glass qualities (4 mm thickness) for covering c-Si photovoltaic cells. Average loss of solar photon flux (300–1100 nm) indicated by dashed lines.

flux loss $(\alpha_p + \rho_p) = 4.4\%$ and a band gap of c-Si at 1.12 eV ≈ 1100 nm, a state-of-the-art single AR-coated low-iron float glass can then transmit more than 95% of the PV-relevant number of photons (Figure 2).

3.3 Double-sided Glass Modules for Building-integrated Photovoltaics

When laminated between two glass panes, PV cells can be integrated in the envelope of a building in the form of balustrades, sunshades, facades, or canopies. The energy balance of the building can thus be improved not only by the conversion of solar energy into electricity but also by the shading function that reduces direct energy transmission through the modules. Since PV cells of the first generation are opaque, changing the distance between them (spacing) allows one to adjust the total light transmission and electricity output of the glazing. In *building-integrated photovoltaics* (BIPV), glazing is commercially produced from thermally strengthened glass panes with an external AR coating. Besides crystalline silicon cells which form larger strings with spacing between the cells, also thin-film a-Si PV cells are used for BIPV. For the latter concept, the cell surface covers practically the total surface of the glazing but allows some light to pass through so that the transmission is about 20%.

3.4 Glass-bearing Front Electrode Materials

Finally, glass is also an important but hidden component to contact both sc- and pc-Si cells to the front side. For this purpose, pastes containing a silver powder and up to 10 wt % of a BaO-, Bi₂O₃-, and ZnO-containing borosilicate glass of low softening temperature dispersed in an organic binder are commonly used. They are deposited via screen printing or other techniques and fired quickly in an infrared belt kiln. Upon firing, the glass initially softens and then dissolves at higher temperatures the metal into its structure in the form of Ag⁺ ions. On the wafer side, the glass etches the thin, AR oxide layer of the wafer, whereas Ag⁺ ions are reduced to Ag⁰ to form a direct contact between silicon and the highly conductive silver metal.

4 Solar Heat

4.1 Irradiance and Working Temperatures

In this type of conversion systems the relevant parameter is the solar energy flux, or irradiance, which is simply the power received per unit area (W/m²). The solar radiation absorbed is primarily used to heat up a transfer medium (liquid or gas). In secondary processes, the heat is

exchanged with another liquid (water heating), stored (molten salts), transformed into mechanical energy, and finally into electric power (steam engine).

Reflectors can be integrated to increase the irradiance by redirection of the sunlight to the receiver. This irradiance ($\dot{Q}_{\text{solar}}$) is then the product of terrestrial insolation, that is the solar power at the latitude of interest (e.g. 1000 W/m for Europe and North America), the collector efficiency, the geometric ratio of the reflector-to-receiver area or solar concentration factor (C), and the unit area per reflector. In case of concentrated solar power systems, C exceeds unity and the temperature of the receiver (T_R) increases with it. In such a chain, the total energy conversion efficiency is the product of those of the individual conversion steps [10].

For the first conversion of solar radiation into heat, the efficiency of the receiver (η_R) is given by $\eta_R = (\dot{Q}_{\text{abs}} - \dot{Q}_{\text{lost}}) / \dot{Q}_{\text{solar}}$, where the absorbed heat $\dot{Q}_{\text{abs}}$ is $\dot{Q}_{\text{solar}}$ times the absorption coefficient of the receiver material, whereas $\dot{Q}_{\text{lost}}$ is governed by the radiative and convective heat losses of the hot receiver. The former loss is proportional to the area of the receiver and the emissivity of the receiver's surface and increases as the fourth power of the receiver temperature according to Stefan-Boltzmann law. For a solar power plant, the second energy conversion is heat-into-mechanical work for which the efficiency is that of a Carnot engine $\eta_{\text{Carnot}} = 1 - T_{\text{cold}}/T_R$ operating between the hot thermal reservoir, that is T_R and the cold thermal reservoir (T_{cold}). Thus, two temperature effects oppose each other as the efficiency of the Carnot cycle increases when T_R increases whereas that of the receiver decreases.

For a given solar irradiance or concentration factor, the optimum receiver temperature is, therefore, lower than the maximum value. It can be determined from the first derivative of the total efficiency with respect to T_R . In this way one finds that the optimum operating temperature of a trough receiver is about 400 °C for oil-based heat-transfer fluids, 550 °C for molten salts or direct steam (C up to 100), and about 1000 °C for tower receivers with $C > 1000$. Whereas (alumino-)borosilicate glass with a CTE of 3–4 ppm/K can be used in the former systems, silica glass with its CTE of 0.5 ppm/K must be selected in the latter (Figure 3). These temperatures have thus important implications for the materials to be used for making the receiving units.

4.2 Rooftop Water Heaters

Currently two types of water-heating systems with rooftop receivers are sharing major market segments in the residential and commercial sectors. These systems differ by the fact that they have in-house heat exchangers and

Figure 3 Glass transition temperature T_g of glasses used in solar-energy conversion systems as a function of the coefficient of thermal expansion CTE and the factor of solar concentration C .

Figure 4 Solar water heaters. Left: rooftop receiver with in-house boiler and heat exchanger for temperate areas (a), rooftop receiver with rooftop heat exchanger for tropical and subtropical regions (b). Right: box receiver (c), evacuated tube receiver (d).

boilers in temperate areas (Figure 4a) and also rooftop exchangers in tropical and subtropical regions (Figure 4b). In both cases glasses are used as cover panes or evacuated tubes in the receiver and as lining in the drinking water-buffer tanks of the heat exchanger.

A box receiver for water heating comprises an insulation layer made up of stone or glass wool (Chapter 9.3), the actual absorber sheet (metal) with a fused meandered pipe loop (copper) and a cover glass pane that seals the metal housing for protection against the surroundings (Figure 4c). To minimize the emissivity ε of the absorber sheet, coatings with a high wavelength selectivity (>15) are used. The wavelength selectivity is the ratio of the absorbed solar radiation between 0.3 and 4 μm to the emitted IR radiation between 4 and 40 μm , where the IR emission is defined as unity minus the IR reflectivity. As a cover, a low-iron soda-lime-silicate pane is used, either an AR-coated float glass or a rolled glass of smooth pattern, which is usually strengthened thermally to increase its mechanical performance.

An evacuated tube receiver unit consists of parallel glass tubes set in a metal frame or – in some products

– of glass tubes placed on top of a parabolic Al-mirror sheet. Each glass tube is double-walled, one-side-closed and evacuated to suppress conductive heat loss (Figure 4d). To reduce also radiative heat loss, the inner surface of the inner wall has a low-emissivity coating typically made of an AlN/AlN-SS/Cu triple layer ensuring $\epsilon < 8\%$ at 80°C . The solar energy transmittance τ_e of the outer borosilicate glass wall should exceed 90% in the 300–2500 nm wavelength range (Figure 5).

A copper heat pipe is centered within the tube, comprising a long hollow pipe with a large-diameter bulb at the top-end. In some other tube receivers, the heat pipe is positioned directly against the inner glass wall on the sun-exposed side, whereas the welded-aluminum heat-transfer fins are curved to track the sunlight throughout the day. Within the closed heat pipe, water is under a pressure lower than 50 hPa to evaporate at around 30°C . The vapor rises to the bulb at the top-end (i.e. outside the glass tube), where its heat is exchanged. Upon condensation of the cold vapor, water runs down to the hot-end of the heat pipe inside the glass receiver, and so on. The evacuated tube ($<1\text{ mPa}$) is usually made from borosilicate glass (Chapter 7.6) with a 50–70 mm diameter and a distance of about 5 mm between the inner and outer walls. The thickness of the walls is 1.6 mm (inner) and 1.8–2.0 mm (outer) and the length is up to 2 m.

The inner surfaces of the drinking-water buffer tank and the solar-heating coils within it are frequently glass-lined. This enameling serves to increase the durability with respect to hot water and to comply with drinking-

water regulations in terms of metal-ion migration. Standard enameling is performed by a two-coat, two-fire technique with a total thickness of about $300\text{ }\mu\text{m}$. Enamels are typically multicomponent glasses of a borosilicate base with suitable CTE and T_g values for the coated steel. Specifically, the enamel must be kept under compressive stresses, which implies that the CTE of the ground-coat enamel is about 3 ppm/K lower than that of the steel, whereas that of the cover-coat enamel is another 0.5–1.5 ppm/K lower. It happens that top-coat enamels of low CTE are rich in network formers, which ensures the desired hydrolytic resistance.

4.3 Solar Thermal-power Plants

Glasses are used in both collector and receiver units of solar thermal-power plants. In most applications a back-side silvered glass mirror collects the solar radiation. For these mirrors, glass is a protective barrier, a light transmitter, and, in part, a structural support, whereas glass tubes (trough) and windows (tower) are integrated in receivers mainly to suppress convective and conductive losses.

For trough receivers, mirrors are bent in a parabolic shape. The solar irradiance is reflected onto the evacuated tube receiver which is positioned on the focus line while the collector tracks the sun from east to west during the day. In tower-power plants, plane glass mirrors (heliostats) are used as rotating reflectors to keep reflecting

Figure 5 Spectral transmittance and solar-energy loss of 4 mm-thick low-iron soda-lime-silicate, borosilicate, and silica glasses used for solar-thermal applications.

sunlight toward the receiver positioned on the top of the tower.

Bent and plane mirrors are made of tempered low-iron soda-lime-silicate float panes of a 2–4 mm thickness with an edge finish for safe handling and mechanical robustness. For parabolic mirrors the plane glass is sag-bent before being strengthened (Chapter 9.2). The glass is then coated in the superstrate configuration. Whether plane or parabolically curved, all mirrors are silvered (usually wet chemically) and the back of the delicate Ag-layer is protected by a copper layer and then by paint layers to assure the high durability of the reflective coating. Along with a solar-energy reflectivity (ρ_e) higher than 94%, the precision of curvature to better than 2.0 mrad and the mechanical shape stability of the parabolic mirrors are key parameters for the reflector efficiency in trough applications. This is particularly evident for the large reflector apertures and smaller diameters of absorber tubes that are required for high-temperature transport fluids such as molten salts ($T_R = 550^\circ\text{C}$).

A tube receiver comprises an evacuated outer glass tube at a residual pressure lower than 0.1 Pa and an inner metal-pipe loop with a low-emissivity coating ($\epsilon < 10\%$ at 400°C). The outer tube is made of AR-coated borosilicate glass of solar energy transmittance τ_e higher than 97% between 300 and 2500 nm. It is commonly of 120–125 mm outer diameter (2–3 mm wall thickness), up to 4 m long, and sealed with fused metal bellows at both ends to account for the higher thermal expansion of the inner absorber pipe. For power plants operating with oil-based heat-transfer fluids (T_R up to 400°C), glass tubes are equipped with getter materials and a noble-gas capsule. The former captures the hydrogen produced by the decomposition of the thermo oil, which permeates through the metal pipe into the vacuum of the glass envelope, whereas the latter injects noble gas at the end of the getter capacity into the glass tube to maintain a low conductive heat loss over an extended operating period.

Tower-power plants can comprise a silica-glass window that encloses the aperture of the receiver and separates two pressure or temperature zones. For pressurized air receivers, the window is dome shaped, whereas for unpressurized volumetric receivers, one must assemble segments of silica-glass tubes as imposed by manufacturing constraints for aperture exceeding 1 m^2 . In both cases, the window is AR-coated to suppress reflective loss [11], whereas temperatures are kept lower than 1000°C by active cooling to reduce inter alia the formation of defects, such as those from surface contaminations that could not be cleaned up [12].

Concentrated solar energy can also be used for steam generation in oilfield operations. Enclosed trough receivers have been developed to protect the reflector and receiver surfaces from windborne sand, dust, humidity,

and other harsh conditions often prevailing in the environment of oilfields [13]. In these steam plants the entire reflector-receiver units are sheltered in agricultural greenhouses. The curved back-side silvered glass mirrors are then replaced under the sealed glass-skinned structure by a lightweight aluminum honeycomb construction. Soda-lime-silica float glass is used for the glazing of the greenhouses, which is kept clean with automated washing machines.

5 Solar Fuels

5.1 Natural and Artificial Water Splitting

A fuel can be defined as a simple chemical reductant, easy to transport and store, which reacts (“burns”) on demand with the oxygen of the air and releases much energy [14]. In contrast to fossil fuels (oil, gas, and coal), which originated in ancient photosynthesis and are stored in geologic deposits, solar fuels are generated by natural and artificial photosynthesis either directly or by fermentation upon short lifetime cycles. The basic process is the direct conversion of solar energy into chemical energy. In photosynthesis, the solar radiation is used to “split” water in the Calvin cycle of the chloroplasts, liberate oxygen, and fix carbon dioxide in carbohydrates, whereas other algae and some bacteria can use other photosystems to reduce in addition protons to hydrogen gas. With respect to natural photolytic processes, the important light-dependent part of the redox reactions of photosynthesis takes place at pigments, such as chlorophyll, where the oxygen atoms of water molecules are oxidized by catalyst structures containing four manganese and one calcium ions. In artificial photosynthesis, photoelectrochemical (PEC) cells utilize other metal catalyzers to overcome the high thermodynamic potential for water splitting (1.23 V under standard conditions and $\text{pH} = 0$). In thermochemical reactors, solar heat is alternatively used to split water into hydrogen and oxygen gas through redox reactions with metal catalysts at higher temperatures.

5.2 Natural Photosynthesis

In energy production, photosynthesis is the direct source of first-generation biofuels made from sugar, starch, or vegetable oil. An example is the production of bioethanol by fermentation of plant-derived sugars from sugar cane or beet. This type of biofuel has been criticized in terms of monocultivation and driver of global food shortage. In second-generation fuels, the biomass thus consists of agricultural and forest residues (e.g. stems, leaves, and husks), food-industry leftovers, or municipal biowaste. Different biochemical/biothermal processes separate

the sugar from lignin, hemicelluloses and celluloses from the woody, fibrous biomass, but they all involve glass-lined reactors and storage vessels. Particularly visible are large silos and biogas digesters of up to 7000 m³ that are frequently made from segmented steel panels glass-lined on both sides to enable easy cleaning and confer to their inner and outer sides a high resistance to acids and atmospheric corrosion, respectively.

Besides, natural water-splitting photosynthesis (biophotolysis) is an attractive route to produce H₂ gas. Processes include the use of oxygenic photosynthetic microorganisms such as genetically engineered green microalgae *Chlamydomonas reinhardtii* [15]. Large-scale algae plants are envisioned for the production of microalgal biomass and bio fuels and simultaneous capture of CO₂, comprising closed zig-zag borosilicate glass pipes and using flue gases from industry as a cheap source of sterile CO₂.

Photobioreactors have already been integrated in the envelope of buildings (e.g. as flat facade elements) not only to improve indoor air quality through O₂ production and CO₂ absorption by algae but also to grow renewable fuel stocks [16]. Such elements can span a full story. They consist of a vertical circa 80 mm-deep glass reactor panel of approximately 2.5 × 0.7 m² made up of three cavities in an aluminum frame. The central cavity has an interspace distance of 18 mm (to be filled with water and algae, serviced through the bottom edge of the panel), whereas the outer cavities are filled with argon for thermal insulation as in a standard double glazing window. The flanking glass panes of the reactor are made from low-iron soda-lime glass, which have been thermally strengthened. The outer sheets consist of a laminated safety glass to catch glass fragments in the event of reactor breakage. Laminates are made of rolled-plate glass sheets to minimize reflections (non-blinding effect) and enable an increase of solar energy gain through micro-patterns (e.g. pyramids) on the sun-exposed surface of the glass [16].

5.3 Artificial Photosynthesis

A promising technology to store solar energy is artificial photosynthesis. Different stages of integration of PV elements into electrochemical cells have been designed. The simplest, physical pathway is H₂ production by electrolysis of water with the electricity produced by PV cells. High solar-to-fuel efficiencies reaching 30% have been reported with triple-junction thin-film PV cells [17]. Depending on the sequence of electrode and semiconductor layers of such multi-junction PV cells, low-iron float-glass is used as hermetic cover in the sub- or superstrate configuration. In addition, Fresnel glass lenses are used to concentrate solar irradiation, which of course

improves the solar-harvesting part of the conversion chain.

For chemical production, the materials for light capture and the water splitting catalysts are in contact to create a wireless PEC cell. Solar radiation then induces photocatalytic reactions at the anode ($4h\nu \rightarrow 4h^+ + 4e^-$) where the oxygen of water is oxidized ($2O^{2-} + 4h^+ = O_2$), whereas hydrogen gas is generated at the cathode ($4H^+ + 4e^- = 2H_2$). Current solar-to-fuel efficiencies are relatively low as they depend strongly on suitable bandgap structures of catalysts such as TiO₂ doped with precious metals, transition metals ligated to certain organic complexes (e.g. tris(bipyridine) cobalt(II)) or bonded to chalcogenides (e.g. WSe₂). For the light-harvesting part, cells frequently include photoelectrodes made from borosilicate glasses coated with films of TCO [18]. Economically, however, much work remains to be done if the production of such PEC cells is to compete with biomass-derived fuels.

5.4 Solar Thermochemical Water Splitting

Alternatively, water can be split by chemical means, thanks to the high temperatures provided by sunlight. In a two-step cycle, a metal oxide is first reduced at high temperatures. Water is then split by oxidation of its reduced form so that the metal oxide acts as a catalyst. Temperatures of 1000–1500 °C are needed for redox-pairs such as ZnO/Zn and CeO₂/CeO_{2-δ}, which require solar concentration factors in the 1000–5000 C range with mirrors that can be arranged in dish, Fresnel, tower, and beam-down configurations. Glass is also required for the receivers, which are rotating cylinders comprising a 12 mm-thick silica-glass window 600 mm in diameter [19]. What is making this route for splitting water decidedly attractive is that the efficiency of converting solar energy into heat can reach 70% at such high temperatures.

6 Solar Water Treatments

6.1 Solar Desalination

Adequate water supply is essential for the human existence and life on Earth. Including ice, however, fresh water is a limited resource since more than 97% of it is the salty water of the oceans. As a result, coastal countries and islands in arid regions rely on sea-water desalination (e.g. Saudi Arabia, Israel). They operate multistage flash (MSF) distillation and reverse osmosis (RO) plants. The former requires heating of the brine and, thus, depends on a thermal-power station, whereas the latter consumes large amounts of electrical energy to pump sea water at

high pressures through membranes. Solar desalination with new kinds of stills thus is an emerging alternative technology for less developed countries and rural locations without access to conventional energy supply systems (gas, oil, and electricity grid). In these stills, float and rolled glass panes are used as double- or single-slope roofs to cover black-painted basins filled with saline water. After evaporation, the fresh water condenses on the inner side of the glass roof and flows toward a distillate trough where it is collected in a vessel, whereas the brine is usually drained. The average yield of distilled water depends on the different external and internal operating parameters. For a basic *passive* solar still (i.e. natural evaporation and condensation) it can reach 2–5 l/m²/d [20]. In *active* solar stills, pumps, fans, or other electrically powered devices are added to boost the performance up to 5–7 l/m²/d [20].

6.2 Solar Disinfection

In most industrialized countries the average water consumption is up to 10 times higher than the recommended basic water requirement for drinking, bathing, cooking, and sanitation services (=50 l/p/d). On the other hand, the World Health Organization (WHO) estimates that more than 1.1 billion people have no access to clean drinking water and 2.4 billion people to an improved sanitation system. For these regions WHO recommends to practice solar disinfection (SODIS), which relies on a combination of heat (infrared component) and UV-A (wavelengths 320–400 nm) of the solar irradiation to destroy bacteria cells, inter alia through pathogen damage caused by UV-A-induced reaction of oxygen to free radicals and hydrogen peroxides [21]. The technique consists in placing surface water into transparent containers, which are then exposed to the sun for a certain time on a corrugated metal roof; a minimum of six hours is recommended under sunny weather conditions to rise temperatures above 50 °C. Plain, clear white glass bottles have the advantage to be heat- and scratch-resistant and free of photoproducts. Polyethylene terephthalate (PET) beverage bottles have in contrast been recently a source of controversy because formaldehyde, acetaldehyde, and antimony appear to migrate from the bottles into fresh water [22]. The time taken for the conventional SODIS process can be greatly reduced through semiconductor-based photocatalysis, for instance, with Cu and N codoped TiO₂ [23]. Current solar reactor designs comprise a series of borosilicate glass tubes and titania-coated glass beads. The glass tubes are used as UV-A transparent containers (Figure 5) in which the transparent glass beads provide large surfaces for photocatalytic degradation of pathogens.

7 Perspectives

The use of glass will keep growing worldwide in solar-energy applications since established as well as emerging technologies require it for mechanically robust and chemically durable envelope structures at high solar-transmittance levels. For PV cells, glass thinner than 2 mm (thermally strengthened at low price) is desired to reduce the weight and to increase the photon efficiency of the modules. In addition, the demand for add-on functionalities of solar glasses is also increasing. But soiling and fouling of glass surfaces are enormous challenges, for which long-term solutions must be sought and implemented. As an example, bifunctional coatings are currently under development to combine AR with photocatalytic properties for self-cleaning [24, 25]. For photobioreactors, light conversion coatings have been introduced, which are promising to increase greatly the photosynthetic activity [26]. Along with solar shifting, integration of fluidic systems into the building envelope will be one of the strategies to gain solar energy in the future. For this application, glasses have to show not only a high optical transparency but also a chemical resistance to corrosive media with respect to architectural lifetime [27]. New concepts, like solar updraft tower plants, will require gigantic glass canopies as 5 km in diameter structures are projected for which ultrastrong glasses must be developed. Finally, with respect to solar energy conversion at higher concentration ratios ($C > 10^3$), glass that could withstand extreme temperatures (>1200 °C) for longer times is a challenge, which remains largely unresolved.

9.5

Sulfide-glass Electrolytes for All-solid-state Batteries

Akitoshi Hayashi and Masahiro Tatsumisago

Department of Applied Chemistry, Faculty of Engineering, Osaka Prefecture University, Sakai, Osaka, Japan

1 Introduction

Development of high-power rechargeable batteries with an elevated energy density is being much stimulated by the rapidly growing demand for not only power-hungry mobile devices but also for automotive propulsion and distributed power-storing systems for solar energy. In this respect, Li-based batteries are potentially the most efficient since lithium is at the same time the lightest and the most electropositive metal, with a potential of -3.04 V vs. the standard hydrogen electrode [1] and, as a fast-diffusing cation, in addition generally ensures a high ionic conductivity (Chapter 4.2). Beginning in the 1970s, nonrechargeable Li cells were thus designed while fundamental research was done on reversible lithium reactions at the electrodes. Building on these practical and theoretical advances, an important step was made in 1991 by the Sony Corporation when it commercialized the first rechargeable lithium-ion battery (LIB). Since then these batteries have widely spread all over the world [1, 2] with their operating voltage of about 4 V and gravimetric energy densities of about 150 Wh/kg, which was twice or three times larger than that of the Ni-MH batteries that were hitherto prevailing.

These batteries are composed of a graphite negative electrode, a lithium transition-metal oxide (LiCoO_2) positive electrode, and an electrolyte made up of a lithium salt such as LiPF_6 dissolved in a solution of ethylene carbonate [$\text{C}_3\text{H}_4\text{O}_3$] and diethyl carbonate [$\text{C}_5\text{H}_{10}\text{O}_3$] (e.g. highly conductive and fluid carbonates, respectively, forming a nonaqueous organic solvent to prevent irreversible oxidation by water of Li into LiOH and release

of hydrogen). An appropriate interface then is simply ensured by the soaking of both electrodes into the electrolyte. Because both LiCoO_2 and graphite electrodes have a layered structure, the electrochemical reactions involved is a deintercalation/intercalation process. They can be expressed as:

with standard potentials of 3.9 and 0.1 V vs. Li^+/Li , respectively. Whereas lithium ions are efficiently mobile between the interlayers of graphite and LiCoO_2 , the structure of the electrodes does not change much upon lithium intercalation/deintercalation. Thanks to the small volume changes involved, this rocking-chair type of system ensures the long cycle lives of LIB, whether with the initial LiCoO_2 electrode or with other oxide compounds currently investigated such as LiMn_2O_4 or LiFePO_4 . But increasingly large-scale application of LIB makes its safety concerns more serious because of the rising amounts of flammable organic liquid electrolytes involved [3]. Although the energy density of LIB has been gradually increased up to 265 Wh/kg through increases of the electrode surface areas or addition of dopants to increase the electrical conductivity, realization of post-LIB with a higher energy density is still strongly desired.

On both safety and performance counts, replacing organic liquids by inorganic solids as electrolytes will be advantageous if at the same time large-capacity electrode materials can be found. Sulfur, which is difficult to use in conventional liquid-electrolyte batteries [4–6], might, for instance, be adopted for the positive electrode

A. Sakuda, National Institute of Advanced Industrial Science and Technology, Tsukuba-shi, Ibaraki-ken, Japan

with a higher capacity than a conventional LiCoO_2 . Besides, interest has also to be paid to sodium, the alkali that is next to lithium in terms of atomic weight and standard potential and is naturally very abundant [7, 8], which is an attractive feature in large-scale applications for stationary load-leveling. In all-solid-state rechargeable batteries, direct stacking of cells in one package will in addition achieve a high operating voltage either with lithium or sodium.

Two key points to realize all-solid-state batteries are the availability of an electrolyte with high Li^+ or Na^+ ion conductivity at room temperature, along with formation of favorable solid–solid interface between the electrode and electrolyte. Now, Li^+ ion-conducting sulfide electrolytes having conductivities similar to the 10^{-2} S/cm typical of organic liquid electrolytes have recently been discovered [9, 10], whereas techniques have been developed for increasing contact area at the interface and, thus, for enhancing the utilization of electrode-active materials and rate capability.

In this chapter, these recent developments pertaining to sulfide glasses as solid electrolytes and to their application to all-solid-state lithium and sodium batteries are thus reviewed. The structure and relevant physical properties of sulfide glasses will first be briefly presented. The fundamental importance of ion conductivity and how this property can be optimized will then be described. Finally, the various ways in which good contact between the electrode and electrolyte may be designed in all-solid-state batteries will also be discussed.

2 Classification of All-solid-state Batteries

The cell voltage is determined by the difference in standard potential between the positive and negative electrodes, and its energy density by the product of this voltage and capacity. For practical purposes, the cell capacity is expressed in units of weight or of volume, including the electrolyte and both positive and negative electrodes. For research purposes, however, one usually considers the capacity referred to the weight of the targeted electrodes. Two types of all-solid-state batteries are widely studied (Figure 1).

A thin-film battery has a thin-film electrode and high charge and discharge rates because of small electrical resistances of both electrode and electrolyte. Thin-film batteries have marked advantages in terms of safety because they do not suffer from leakage and flammability. Although they have in addition long cycle lives and versatile geometries, their energy density and practical usefulness are by definition limited by the small weight of the electrode films.

Thin-film batteries are composed of electrode and electrolyte thin films prepared by RF sputtering or laser ablation. Good contact between the electrodes and electrolyte thin films is achieved by gas-phase deposition techniques. With *Lithium Phosphorus OxyNitride* (LiPON) glass electrolytes having a lithium ion conductivity with good chemical and electrochemical stability, thin-film batteries

Figure 1 Comparison between the structure of thin-film (a) bulk-type (b) all-solid-state batteries.

have shown excellent long-term performances over 30 000 cycles [11]. Even though its ambient-temperature conductivity of about 10^{-6} S/cm is not so high, LiPON may be used in these batteries because one can keep the total resistance of the electrolyte small by reducing its thickness.

To increase inherently the cell capacity, use of thick electrode layers with large amounts of electrode-active materials is required. For large-size energy-storage devices with a high energy density, this combination is achieved in all-solid-state bulk batteries. For the electrolyte, particular interest has been paid to oxides and sulfides because they are well suited to satisfy five (at least) important requirements: high ambient-temperature conductivity, wide electrochemical window (i.e. voltage range where the substance is neither reduced nor oxidized), good formability (processability), favorable mechanical properties, and good chemical stability. Sulfide solid electrolytes are advantageous with respect to the first four requirements. As for the last, they do suffer from their poor chemical stability in air but this defect can be remedied by appropriate compositional adjustments.

A good electrode–electrolyte interface is easily obtained with a liquid electrolyte, but not with solid electrolytes for which intimate mixing of the two components in the form of powders must be achieved (Figure 1b). The alkali ions are then supplied from the solid electrolyte to the electrode-active material through which the electrons are mobile. Adding a conductive substance such as acetylene black (AB) to the electrode layers is, for instance, needed to ensure electron conduction pathways within electrode-active materials having poor

electronic conductivities. In practice, one fabricates bulk-type all-solid-state batteries by sandwiching a solid electrolyte layer acting as a separator between positive and negative electrode layers and then uniaxially cold pressing them at room temperature. The good electrochemical performance of Indium/LiCoO₂ batteries made in this way with Li₂S–SiS₂–Li₃PO₄ glass electrolytes were reported in 1994 [12]. Since then, as will be described, similar cells with sulfide electrolytes have been developed with better still performances.

3 Sulfide Glasses

3.1 Structure and Properties

The conductive and mechanical properties of glass electrolytes are closely related to their bonding and structure. The structure of glasses in the Li₂S–P₂S₅ and Li₂O–SiO₂ systems are, for instance, described in a similar way since addition of Li₂S causes a depolymerization of the network formed by thiophosphate PS₄^{3–} tetrahedra through the transformation of bridging into nonbridging sulfurs whose negative charge is compensated by Li⁺ ions. Owing to weaker Li–S and P–S bonds compared to Li–O and Si–O bonds resulting from the greater polarizability of the sulfide ion, however, sulfide glasses have electrical conductivities higher than those of their oxide counterparts by up to five orders of magnitude (cf. Table 1).

For the same reason, their Young moduli are typically 10 times lower. As determined from ultrasonic measurements, Li₂S–P₂S₅ glass electrolytes have a Young modulus of about 20 GPa [13]. This value is intermediate

Table 1 Li⁺ ion and Na⁺ ion conductivities for typical oxide and sulfide solid electrolytes.

Li ⁺ ion conductor			Na ⁺ ion conductor		
Classification	System	Conductivity (25 °C, S/cm)	Classification	System	Conductivity (25 °C, S/cm)
Oxide glass	60 Li ₂ O·40 SiO ₂	3×10^{-6}	Oxide glass	Na ₂ O–SiO ₂	2×10^{-7}
Oxide crystal			Oxide crystal		
NASICON	Li _{1.3} Al _{0.3} Ti _{1.7} (PO ₄) ₃	7×10^{-4}	NASICON	Na ₃ Zr ₂ Si ₂ PO ₁₂	1×10^{-3}
Perovskite	Li _{0.34} La _{0.51} TiO _{2.94}	1.4×10^{-3}	NASICON	Na ₃ Zr _{1.88} Y _{0.12} Si ₂ PO _{11.94}	2.5×10^{-3}
Garnet	Li ₇ La ₃ Zr ₂ O ₁₂	3×10^{-4}	β-alumina	Na ₂ O·11 Al ₂ O ₃	1.2×10^{-3}
Sulfide glass	75 Li ₂ S·25 P ₂ S ₅	4×10^{-4}	Sulfide glass	50 Na ₂ S·50 SiS ₂	1×10^{-5}
Sulfide crystal	Li ₁₀ GeP ₂ S ₁₂	1.2×10^{-2}	Sulfide crystal	Na ₃ PS ₄ (tetragonal)	1×10^{-6}
Sulfide	70 Li ₂ S·30 P ₂ S ₅	1.7×10^{-2}	Sulfide	75 Na ₂ S·25 SiS ₂	4.6×10^{-4}
Glass-ceramic	80 Li ₂ S·20 P ₂ S ₅	1.3×10^{-3}	Glass-ceramic	94 Na ₃ PS ₄ ·6 Na ₄ Si ₃	7.4×10^{-4}

Source: Data from [6].

between those of typical oxide glasses (Chapter 3.11) and organic polymers (Chapter 8.7). It is low enough for alkali sulfide glasses to deform elastically and, thus, to accommodate much more readily volume changes of the electrode reactions with the alkalis. As a result, most all-solid-state batteries with sulfide solid electrolytes keep good interface contact and, thus, exhibit the good cycle performance needed to ensure long cycle lives [6, 8]. Likewise, their glass transition temperatures of about only 200 °C makes them much easier to process.

Of course, the most direct strategy to increase the conductivity of glass electrolytes is to increase the number of mobile ions through an increase of the alkali-ion concentration. In the Li_2S – P_2S_5 system, the highest conductivity is achieved for the 75 mol % Li_2S composition [ortho-thiophosphate] for which the glass is composed of isolated ions of Li^+ cation and PS_4^{3-} tetrahedra. This structure is favorable for facile ion conduction, thanks to the intrinsic free volume of the glass structure.

3.2 Preparation Techniques

Sulfide-glass electrolytes are usually prepared with the quenching method. For materials with a high Li^+ ion concentration, however, quenching at a rate higher than 10^5 K/s with a twin-roller apparatus is needed to inhibit crystallization upon cooling and, thus, to expand the glass-forming region [14]. In the Li_2S – P_2S_5 system, glasses can generally be prepared in this way but the melting reaction has to be carried out in sealed quartz tubes because of the high vapor pressure of P_2S_5 at elevated temperatures. For these glasses, mechano-chemical synthesis from crystalline forms with a planetary ball-mill apparatus then is an advantageous alternative because the whole process is performed at room temperature. Fine electrolyte powders, which can be directly applied to solid-state batteries, are obtained in this manner without an additional pulverizing step [5, 6]. As an example, the 75 Li_2S ·25 P_2S_5 (mol %) glass is readily prepared via mechano-chemistry but is difficult to obtain by melt quenching. Raman spectra do indicate that the local structure around phosphorus is almost the same in glasses prepared with both methods.

3.3 Chemical Stability

A drawback of sulfide electrolytes is their low chemical stability with respect to atmospheric water. The amount of H_2S generated from Li_2S – P_2S_5 glasses in fact depends on composition. Selection of a suitable glass with a structure resisting hydrolysis is effective in suppressing H_2S gas generation [15]. Lithium *ortho*-thiophosphate Li_3PS_4 glass, for instance, has the best stability in the Li_2S – P_2S_5 system. Stability in air can also be improved by partial

substitution of oxides (Li_2O or P_2O_5) for sulfides (Li_2S or P_2S_5), but addition of Li_2O causes a monotonous decrease of the conductivity. To counter this effect, LiI has been added to Li_2O – Li_2S – P_2S_5 glasses, with the result that 30 LiI ·70(0.07 Li_2O ·0.68 Li_2S ·0.25 P_2S_5) glass has a high conductivity of 1.3×10^{-3} S/cm at 25 °C with the same chemical stability as 7 Li_2O ·68 Li_2S ·25 P_2S_5 .

Metal oxides M_xO_y (Fe_2O_3 , ZnO , and Bi_2O_3) are also efficient stabilizers because of their large negative Gibbs free energies of reaction with H_2S . Likewise, Li_4SnS_4 -based sulfide electrolytes have good chemical stability [16], especially through partial substitution of As for Sn, with which conductivities of 10^{-3} S/cm are achieved. These results conform to the HSAB theory of Pearson [17] according to which soft acids of Sn and As preferentially react with soft bases such as sulfur, rather than with hard acids of oxygen.

4 Sulfide Glasses as Solid Electrolytes

4.1 Electrical Conductivity

In sulfide-glass electrolytes, electrical conduction is slower at grain boundaries than in the bulk of the grains so that it varies with frequency (Figure 2), the low-frequency plateau being relevant for battery operations. The Li^+ and Na^+ ion conductivities obtained in this way at 25 °C for typical oxide and sulfide solid electrolytes are summarized in Table 1. These electrolytes are either glassy or crystalline. In general, the former show a relatively high conductivity in a wide composition range, thanks to the intrinsic free volume where the targeted Li^+ or Na^+ ions can move readily. For a given glass series the highest conductivity is then reached when the number and mobility of charge-carrier ions is maximum. In this respect, the ionic conductivity drastically increases from oxide to sulfide glasses as exemplified by the contrast between Li_2S – SiS_2 (ca. 10^{-4} S/cm) and Li_2O – SiO_2 ($>10^{-6}$ S/cm) glasses. The reason is that lithium ions, acting as a “hard acid” in the HSAB theory [17], are more mobile in a glass matrix of sulfide ions, which act as a “soft base.”

These Li_2S – SiS_2 glasses are thus attractive solid electrolytes whose conductivity can be further increased to ca. 10^{-3} S/cm by addition of either lithium halides such as LiI or lithium *ortho*-oxosalts such as Li_3PO_4 or Li_4SiO_4 . That lithium sulfide solid electrolytes have a unity transference number is another advantage: although commercially available organic liquid electrolytes show room-temperature conductivities of 10^{-2} S/cm, their lithium transference number is lower than 0.5. With a similarly high ion conductivity of 10^{-2} S/cm, lithium sulfide electrolytes are thus preferable for high-rate rechargeable batteries.

Figure 2 Relationship between the electrical conductivity and the microstructure of glass-ceramics. (a) Frequency dependence of the room-temperature conductivity (σ') of Na_3PS_4 glass and glass-ceramic electrolytes, the apparent decrease at the lowest frequencies being due to electrode polarization. Conductivities for a powder-compressed pellet of β -alumina at 70 and 120 °C are included for comparison. (b) and (c) Cross-sectional SEM images for powder-compressed pellet of Na_3PS_4 glass-ceramic and β -alumina, respectively.

4.2 Conductivity Optimization

In contrast, the conductivity of crystalline electrolytes strongly depends on the crystal structure so that it is highest for well-defined chemical compositions and heat treatments. A conductivity of more than 10^{-3} S/cm is, for instance, found in $\text{Li}_{0.34}\text{La}_{0.51}\text{TiO}_{2.94}$ perovskite, whereas that of sulfides such as $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$ is higher than 10^{-2} S/cm. Thanks to such elevated values, the maximum conductivity of 10^{-3} S/cm of sulfide-based glasses at room temperature can be increased through partial crystallization [5, 6]. In Li^+ ion conductors, heating of 70 Li_2S :30 P_2S_5 (mol %) glass at 240 K causes $\text{Li}_7\text{P}_3\text{S}_{11}$ to precipitate as a primary phase. The resulting glass-ceramics has a conductivity higher than 10^{-3} S/cm. Upon further heating at 360 °C, the $\text{Li}_7\text{P}_3\text{S}_{11}$ crystallinity increases so that, under optimum synthesis conditions, a conductivity of up to 1.7×10^{-2} S/cm at 25 °C can be achieved [10]. Importantly, however, higher temperatures are to be avoided as $\text{Li}_7\text{P}_3\text{S}_{11}$ completely decomposes upon heating up 550 °C: thermodynamically stable phases such as $\text{Li}_4\text{P}_2\text{S}_6$ then form and cause a conductivity decrease.

With the metastable $\text{Li}_{3.25}\text{P}_{0.95}\text{S}_4$ phase (thio-LISICON $\text{Li}_{3.25}\text{Ge}_{0.25}\text{P}_{0.75}\text{S}_4$ analog) as a solid electrolyte, the 80 Li_2S :20 P_2S_5 (mol %) glass has by comparison a conductivity of 10^{-3} S/cm, which is lower than that of the aforementioned 70 Li_2S :30 P_2S_5 glass-ceramics. This contrast highlights a basic difference between electrolytes made up of glass-ceramics, whose conductivity is strongly related to their crystalline phases, and those made up of glasses, where it simply depends on the lithium ion concentration. As determined by Rietveld analyses of synchrotron XRD measurements, $\text{Li}_7\text{P}_3\text{S}_{11}$ has a triclinic unit cell with the $P-1$ space group and is made up of

P_2S_7 ditetrahedra and PS_4 tetrahedra similar to those of the Ag^+ ion conductor $\text{Ag}_7\text{P}_3\text{S}_{11}$ (monoclinic, space group C2/c). The lithium atoms are located around the P_2S_7 ditetrahedra and PS_4 tetrahedra are surrounded by three to five sulfur atoms. By heating a supercooled liquid of glass electrolyte, one tends to precipitate as a primary crystal either a metastable or a high-temperature phase with a high conductivity.

A high-temperature α -AgI phase with an extremely high Ag^+ ion conductivity is also stabilized at room temperature by crystallization of AgI-based oxyhalide glasses [18]. Glass electrolytes are thus quite useful as precursors for precipitating superionic crystals, which are difficult to synthesize by conventional solid-state reactions.

If the conductivity is lower for Na^+ - than for Li^+ -ion glasses (Table 1), the opposite holds true for crystals with *Na* Super Ionic Conductor (NASICON)-type structures. As an example, the NASICON phases $\text{Na}_3\text{Zr}_2\text{Si}_2\text{PO}_{12}$ and $\text{Li}_{1.3}\text{Al}_{0.3}\text{Ti}_{1.7}(\text{PO}_4)_3$ have Na^+ - and Li^+ -ion conductivities of 10^{-3} and 7×10^{-4} S/cm, respectively. But studies of sulfide crystalline materials with Na^+ -ion conduction are still limited so that improvements can be expected. Although tetragonal Na_3PS_4 has, for instance, a conductivity of only 10^{-6} S/cm, cubic Na_3PS_4 has been precipitated from Na_3PS_4 glass to form a glass-ceramic electrolyte with a much higher conductivity of 4.6×10^{-4} S/cm at 25 °C. In addition, replacement of 6 mol % Na_3PS_4 by Na_4SiS_4 further increases the conductivity to 7.4×10^{-4} S/cm at room temperature. This value is the highest achieved for Na^+ ion conduction in sulfide materials reported so far, presumably as a result of the creation of interstitial Na^+ ions by partial substitution of Si^{4+} for P^{5+} in the network. Detailed structural analyses of the precipitating crystals are thus needed to optimize the conductivity of glass-ceramic electrolytes.

4.3 Electrochemical Window

Of particular interest is the electrochemical window (Chapter 5.10) wider than 5 V measured by cyclic voltammetry for $\text{Li}_2\text{S}-\text{P}_2\text{S}_5$ glass-ceramic electrolytes. To determine it, a stainless-steel disk acting as a working electrode and a lithium foil working as a counter electrode are attached on each face of a pelletized 70 Li_2S :30 P_2S_5 glass-ceramics. A cathodic and an anodic current flow caused by lithium deposition and dissolution, respectively, are observed reversibly at around 0 V (vs. Li^+/Li). Notwithstanding the current caused by this dissolution/deposition process, no current is observed over the whole -0.1 to 5.0 V range. Hence, the $\text{Li}_2\text{S}-\text{P}_2\text{S}_5$ glass-ceramic electrolyte is not prone to oxidation decomposition and shows good compatibility with lithium deposition and dissolution.

4.4 Formability

Good contact at the solid-solid interface between the electrode and electrolyte is a key to improving the performance of all-solid-state batteries. In this respect, too, sulfide electrolytes are advantageous in terms of grain boundaries and solid-solid contacts achieved without any heat treatment. By only cold pressing, a 90% relative density is, for example, achieved at a pressure of 360 MPa when starting with 75 Li_2S :25 P_2S_5 (mol %) pellets. The material is made up of lithium (Li^+) and thiophosphate ions (PS_4^{3-}), which are thought to diffuse at the particle boundaries so as to increase grain size, reduce voids and eventually make grain boundaries hardly visible once densification is achieved through this *room-temperature pressure sintering* process [8].

The importance of this effect is shown by a comparison (Figure 2) made between the conductivities of pressure-sintered Na_3PS_4 glass-ceramics with those of Na_3PS_4 glass and β -alumina, a typical Na^+ ion conductor. For this last material, the low-frequency conductivity of sintered pellets is 1.2×10^{-3} S/cm at 25 °C (Table 1) and that of simply compressed powders is many orders of magnitude lower at 70 and 120 °C (Figure 2) and cannot even be measured at 25 °C. The reason is that one cannot reduce the grain-boundary resistance at room temperature, but need to sinter the material above 1000 °C. The advantage of the Na_3PS_4 glass-ceramic is thus obvious since in the form of compressed powders its conductivity is 10^{-4} S/cm at 25 °C and further increases at temperatures of 70–120 °C. This difference between β -alumina and Na_3PS_4 glass-ceramics clearly correlates with the poor and excellent grain contact visible in the former and latter, respectively (Figure 2).

In this respect, glass electrolytes have the important advantage of ready softening at temperatures close to

glass transition. At such temperatures grain boundaries and voids almost disappear in a 80 Li_2S :20 P_2S_5 (mol %) glass upon compaction, causing the room-temperature conductivity to increase to 8.8×10^{-4} S/cm from the 3.7×10^{-4} S/cm of a cold-pressed sample.

5 Bulk-type Batteries with Sulfide Electrolytes

5.1 Electrodes

In commercially available lithium-ion batteries, the positive and negative electrodes are typically LiCoO_2 and graphite, respectively, but spinel-type $\text{Li}_4\text{Ti}_5\text{O}_{12}$ is also used as a negative electrode. These materials remain used in all-solid-state batteries. As an example, In/ LiCoO_2 or Li-In/ $\text{Li}_4\text{Ti}_5\text{O}_{12}$ cells with a $\text{Li}_2\text{S}-\text{P}_2\text{S}_5$ glass-ceramic electrolyte operated as a rechargeable battery at 25 °C under a limited current density of 0.064 mA/cm² keeps a charge-discharge efficiency of 100% for several hundred cycles [5]. Under a current density higher than 10 mA/cm², a discharge-charge capacity of about 140 mAh/g has been maintained in the latter cell at 100 °C without degradation for 700 cycles [5]. As the sulfide-glass-ceramics is thermodynamically stable at 100 °C, the cell resistance decreases and the rate performance is thus improved with an increase in operating temperature.

All-solid-state sodium cells with Na_3PS_4 glass-ceramic electrolytes also operate as a rechargeable battery at room temperature [8, 19]. An Na-Sn alloy is used as a negative electrode and transition metal sulfides such as TiS_x as a positive electrode. Sodium cells with amorphous TiS_3 have a capacity of 300 mAh/g, which is three times higher than that of crystalline TiS_2 (a typical positive electrode-active material), and retain this capacity for several cycles. Thanks to its structural flexibility and free volume, amorphous TiS_3 electrodes are thus effective for intercalation of both sodium and lithium ions in all-solid-state cells.

In summary, bulk-type solid-state cells inherently exhibit an excellent cycle performance and high-rate operations at elevated temperatures at which conventional lithium-ion batteries with organic liquid electrolytes are difficult to use.

5.2 Interfacial Resistance

A problem encountered in electrolyte-electrode contacts is that an interfacial resistance manifests itself after the initial charging process. For a LiCoO_2 electrode and a $\text{Li}_2\text{S}-\text{P}_2\text{S}_5$ electrolyte, coating of the electrode particles by Li^+ ion-conductive oxide films such as LiNbO_3 on LiCoO_2 is, for instance, an effective way to decrease this resistance and, thus, to enable cell operation at current

densities higher than 1 mA/cm^2 [20]. When examined by cross-sectional TEM-EDX techniques (Chapter 2.3) after charging, the electrode–electrolyte interface shows the presence of an interfacial layer. Acting as buffer layers, the coatings could then either suppress it or inhibit its formation [21]. Surface coating of active material particles with oxide thin-films thus is useful to improve the rate capability of all-solid-state batteries [20, 21], but the effect requires coating with high-conductivity ions. As an example, one reduces more effectively the interfacial resistance by coating with a $\text{Li}_{3.5}\text{Si}_{0.5}\text{P}_{0.5}\text{O}_4$, whose conductivity is 10^{-6} S/cm than with Li_2SiO_3 or SiO_2 .

Likewise, CoS or NiS coatings on LiCoO_2 decrease the interfacial resistance after charging. These metal sulfide coatings also act as buffer layers that suppress degradation at the highly reactive interface between charged LiCoO_2 and the Li_2S – P_2S_5 electrolyte. This result implies that cobalt sulfides, which are presumably interfacial compounds, do not cause the interfacial resistance but rather the degradation of the solid electrolyte and/or the LiCoO_2 electrode at the interface. Although the influence of a space charge layer on the interfacial resistance remains to be clarified, structural deterioration at interfaces after cycling is actually observed, which is a main cause of the increase in the interfacial resistance.

6 Interfacial Design

As already noted, electrode–electrolyte interfaces must be suitably designed for ensuring effective charge-transfer reactions and, thus, good charge–discharge performances of all-solid-state batteries. Increasing the contact area between the electrode and electrolyte is needed to achieve larger capacity. Three approaches can be followed in this respect (Figure 3).

6.1 Surface Coating of Solid Electrolyte on Active Material Particles

To achieve large contact areas between the Li_2S – P_2S_5 solid electrolyte and the LiCoO_2 active material, the former can be coated on the latter by pulsed laser deposition (PLD). The resulting decrease of the solid electrolyte content is useful for increasing the energy density of solid-state cells. As an example, coating of LiCoO_2 particles with a 80 Li_2 ·20 P_2S_5 (mol %) solid electrolyte is carried out by PLD with a KrF excimer laser ($\lambda = 248 \text{ nm}$) as sketched in Figure 3a. A pelletized mixture of Li_2S and P_2S_5 crystalline powders was used as a target whereas the LiCoO_2 particles were first coated themselves with

Figure 3 Sketch of three procedures used to ensure favorable electrode–electrolyte interfaces.

LiNbO₃ film to decrease the interfacial resistance after charging. During the deposition, the LiCoO₂ particles were fluidized by a vibrator in order to form a uniform solid electrolyte layer on them. According to the cross-sectional TEM image of Figure 3a, this film has a thickness of about 70 nm and shows good adhesion to the surface of the LiNbO₃-coated LiCoO₂ particles. Its conductivity is about 10⁻⁴ S/cm at 25 °C.

The In/80Li₂S-20P₂S₅ glass-ceramics/LiCoO₂ cells prepared in this way can be charged and discharged and retain their initial capacity for several cycles, whereas similar cells with noncoated electrodes do not work because of insufficient lithium ion conduction pathways to LiCoO₂. Another advantage of the process is the 3 wt % solid electrolyte coating in the LiCoO₂ working electrode, which allows the energy density of the cell to be increased up to ca. 280 Wh/kg (normalized by the weight of LiCoO₂ positive electrode layer). For comparison, without coating one needs to add 30 wt % solid electrolyte particles to operate typical solid-state In/LiCoO₂ cells, in this case with a lower energy density of ca. 230 Wh/kg.

Alternatively, favorable electrode–electrolyte interfaces can be more simply obtained from liquid-phase synthesis of the electrolyte. From the reaction of Li₂S and P₂S₅ in a mixture of *N*-methylformamide [C₂H₅NO] and *n*-hexane [C₆H₁₄], a yellow solution is obtained (Figure 4) which, upon mixing with LiCoO₂ particles and drying at 180 °C for three hours under vacuum, yields electrodes with a 7.5 wt % solid electrolyte coating [22]. Without addition of solid electrolyte and conductive additive particles to the positive electrode, a cell made in this manner is rechargeable with an initial discharge capacity of 32 mAh/g. This value is still small at the

present stage because the solid electrolyte has a low conductivity of about 10⁻⁶ S/cm, but work is underway to improve the situation.

6.2 Ball-milling Prepared Nanocomposites

As already noted, high-energy planetary ball-milling is often used for preparing nanocomposite electrolytes. In particular, one obtains favorable interfaces between the solid electrolyte and the active materials with the help of conductive additives such as nanocarbon materials to improve the low lithium and electronic conductivities. Sulfur and Li₂S are attractive positive electrode materials with theoretical high capacity of 1672 and 1170 mAh/g, respectively. The latter compound is a discharge product of the sulfur-active material as described by the reaction $S + 2Li^+ + 2e^- \leftrightarrow Li_2S$. Like LiCoO₂, Li₂S is a lithium source so that its use as a positive electrode should be advantageous in terms of battery versatility and cycleability when combined with a Li-free negative electrode material such as graphite. Both sulfur and Li₂S are insulators, however, so that nanocomposites with carbon conductive additives should be needed to incorporate these active materials.

Recently, sulfur and Li₂S have been studied for Li/S batteries with high energy density, but the use of these active materials is difficult because the electrochemically formed lithium polysulfide (Li₂S_x) species easily dissolve in conventional organic liquid electrolytes. Such a reaction does not take place in solid electrolytes, as illustrated by a mixture of Li₂S active material, Li₂S–P₂S₅ solid electrolyte, and AB (conductive additive) ground with a planetary ball-mill apparatus. The cross-sectional STEM-EELS mappings reveal that the particles form a nanocomposite material where Li₂S (ca. 200 nm in size) and AB (ca. 100 nm in size) domains are dispersed and embedded in the solid electrolyte matrix (Figure 3).

The charge–discharge curves of all-solid-state cells with S or Li₂S active material at 25 °C under a current density of 0.064 mA/cm² are shown in Figure 5. The weight ratio of S or Li₂S, Li₂S–P₂S₅ solid electrolyte, and AB are 25 : 50 : 25. The Li-In/S cell exhibits a large reversible capacity of over 1500 mAh/g of sulfur with an average potential of ca. 2.1 V (vs. Li⁺/Li). Similar charge–discharge profiles are observed in the In/Li₂S cell. The reversible capacity is lower than that of the Li-In/S cell because of smaller theoretical capacity of Li₂S. The charge–discharge curves of a typical all-solid-state In/LiCoO₂ cell are also shown in Figure 5. The cell with a sulfur electrode shows a capacity 15 times higher than that with LiCoO₂, although the operating potential of the former is almost half that of the latter, since the energy density is the product of the cell

Figure 4 Initial charge–discharge curves of all-solid-state In/LiCoO₂ cells using solid electrolyte-coated LiCoO₂ via *N*-methylformamide solution. Inset: photograph of the NMF solution prepared from Li₂S and P₂S₅.

Figure 5 Charge–discharge curves of all-solid-state Li-In/S and In/Li₂S cells at 25 °C under the current density of 0.064 mA/cm². Curves for the cell with a typical positive electrode of LiCoO₂ are also shown for comparison. Inset: cycle performance of the Li-In/S cell at a higher current density of 0.64 mA/cm².

capacity and operating potential. In Figure 5, the inset shows the cycle performance of the Li-In/S cell at 25 °C under a higher current density of 0.64 mA/cm². Good cycleability at 25 °C is apparent. The capacity still is 1000 mAh/g after 200 cycles, suggesting that the use of solid electrolyte is essentially useful for developing Li/S batteries with high energy densities and long cycle lives. The charge–discharge mechanism of the In/Li₂S cell has been explained in terms of TEM observations [23] according to which a high capacity is thanks to reversible reaction between crystalline Li₂S and amorphous sulfur in the positive electrode.

6.3 Use of the Supercooled Liquid State

As already noted in Section 4.4, the softening technique ensures good contact at the electrode–electrolyte interface, thanks to the viscous flow of the supercooled liquid electrolyte onto the electrode-active materials. Upon cooling to room temperature, the contact is maintained, as shown by SEM micrograph cross sections of a pelletized mixture of LiCoO₂ and Li₂S–P₂S₅ glass (Figure 3c) kept at 210 °C for four hours. As compared with observations made on the sample before heat treatment, these images do indicate that the grain-boundaries and pores among the LiCoO₂ particles are filled with softened glass domains. That an all-solid-state cell with a heat-treated LiCoO₂ electrode exhibits a larger reversible capacity than a cell without heat-treatment thus is readily accounted for.

7 Perspectives

Commercial production of all-solid-state batteries is not expected before the early 2020s because it still requires to improve both the conductivity and electrochemical–chemical stability of sulfide electrolytes. In addition, facile approaches for achieving favorable electrode–electrolyte interfaces are needed. A solid-electrolyte coating technique via a liquid-phase process is a cost-effective route to form close interfaces with large contact areas. Further studies about suitable solvents and reaction mechanism are thus required. The control of the size, morphology, and dispersibility of both solid electrolyte and electrode-active material particles are also important for assembling large-sized and stacked batteries. With respect to natural resources and cost, sodium would be advantageous since it is the sixth most abundant element in the Earth’s crust with an abundance of 2.63 %, which is 660 times larger than that of Li [2]. All-solid-state sodium-sulfur batteries with Na₃PS₄ solid electrolyte consisting of only the abundant elements Na, P, and S are fascinating rechargeable batteries from the viewpoint of long-term availability of elements. Our preliminary experiments give a possibility of all-solid-state Na/S batteries with a large capacity of ca. 1200 mAh/g of sulfur-active material at room temperature. Room-temperature operating Na/S batteries would meet a demand for grid application and distributed storage at individual houses. All-solid-state Li or Na batteries with high energy density may replace lithium-ion batteries because of their intrinsic high safety and good cycleability, which meet the demands of large-sized rechargeable batteries for electric cars and distributed power sources at individual houses. But further development in both materials and fabrication technology is needed for commercialization of such solid-state batteries.

The World of the Flat-glass Industry

Key Milestones, Current Status, and Future Trends

Bernard J. Savaète

BJS.Différences, Courbevoie, France

1 Introduction

Flat glass has long been segmented into plate and sheet types. Traditionally, the former was cast and then ground and polished whereas the latter was made with the cylinder and crown processes, which were eventually replaced by drawn processes in the early twentieth century (Chapter 10.9). As developed in Britain by Pilkington Brothers in the 1950s, float glass revolutionized the flat-glass industry (Chapter 1.4). When the process became widely licensed in the early 1960s, it quickly dominated the market in developed countries at a time when a rapidly growing demand made economically not too costly the switch to the new technology from the old processes, which had become obsolete for most purposes.

Nowadays, flat glass is utilized not only in windows and facades for buildings but also in a variety of end products such as windscreens and windows for transportation vehicles, furniture and appliances, solar panels, and many other applications among which electronics is currently sustaining an extremely strong growth. Some of these applications have specific requirements, for instance, a maximum transparency for solar cells (Chapter 9.4) or a thickness of a fraction of 1 mm for the various glass plates of display panels (Chapter 6.10), which has made room for the development of other processes (Chapter 1.4).

In this respect, the important point is that this evolution has taken place at an unprecedented rate. In parallel, new companies have emerged as a result of the very strong economic growth of Asia. The purpose of the present chapter thus is to review the rapidly changing situation and the economic challenges it is raising. Although the main features concerning the history of

the fabrication of flat glass are discussed in detail in another chapter (Chapter 10.9), it will be useful first to summarize them to put the long-term evolution of the processes in perspective. The impact of the float-glass revolution will then be reviewed and conjectures about the future of the flat-glass industry be presented.

2 A Short Overview: Processes and Products

2.1 From the Beginnings to the Mid-nineteenth Century

Some important early steps in glassmaking are summarized in Table 1. The remains of flat-glass panels made 20 centuries ago have been found in houses at Pompeii and Herculaneum (Chapter 10.3). The mediocre quality and high cost of the cast glass used for this purpose prevented its extensive use; however, in contrast to the vessels of any shape and size that came to be widely produced after the very first revolution in glassmaking represented by the invention of blowing toward the beginning of our era (Chapter 10.3). Hence, it was only with church windows that much later flat glass became common in the Middle Ages in the form of stained glass made not too far away by the crown or cylinder processes (Chapter 10.8). Italy, and particularly Venice, then played a key role in the development of the flat-glass industry when, during the Renaissance, mirrors were produced with a tin-mercury amalgam as a reflecting layer. For cost reasons, however, house windows were not widely equipped with flat glass before the eighteenth century in Western Europe.

In the early nineteenth century, the Industrial Revolution provided larger quantities of flat glass across Western Europe. The 1851 “Crystal Palace Exhibition,” in London, specially stimulated the glass industry with its gigantic

Table 1 Early key technological milestones for flat glass.

Date	Innovation	Place
First century BCE	Glass blowing	Middle East
First century	Glass windows at Pompeii	Italy
First century	Production of flat glass by cylinder and crown processes	Europe
Eleventh century	Glass for cathedrals and abbeys – church windows	Europe
Twelfth century	Venetian regulation of glass trade	Italy
Fifteenth century	Cristallo – clear glass at Venice	Italy
1500s	Venetian mirrors	Italy
1612	<i>L'Arte Vetraria</i> , by Antonio Neri (1576–1614)	Italy
1615	Replacement of wood by coal as a combustible	England
1688	Table cast glass by Bernard Perrot [Perotto]	France
1791	Leblanc process for production of soda ash (first revolution)	France

Table 2 Key technological milestones from the mid-eighteenth to the mid-nineteenth century.

Date	Innovation	Place
1840	Silver replacing mercury-tin amalgams for mirrors	UK
1851	Crystal Palace (London)	UK
1860	Stetson patent for double-pane insulating glass	USA
1863	Solvay process improving soda ash production	Belgium
1867	Siemens continuous furnace (second revolution)	UK
1870	De la Bastie process for tempered glass	France
1898	Wired glass “Georgian Wired Glass”	UK
1905	Fourcault sheet process (third revolution)	Belgium
1910	Bicheroux process (glass rolled between rollers)	Germany
1900s	First windscreens for automobiles	—
1910s, 1920s	Safety glass (laminated and tempered)	Europe, USA
1917	Colburn (Libbey Owens) sheet process	USA
1920s	Perception of glass as a modern material	Europe
1925	Pittsburg process for Pennvernon sheet glass	USA
1935	Twin (continuous grinding and polishing on both faces)	UK
1940	First patent on pyrolytic coatings	USA
1940	Fabrication of double-pane insulating glass	USA, Europe
1959	Float by Pilkington (fourth revolution)	UK

greenhouse-like building that covered almost 20 acres (about 81 000 m²) and used some 400 tons of sheet glass [1]. At the same time, the rate of innovation increased tremendously as seen by even a quick comparison between the lists of Tables 1 and 2. Of course, it was the increasing demand for flat glass that initially drove these innovations, which in turn increased the demand for glass as a result of the better quality and lower price that they ensured and of the new applications they made possible.

Of particular interest has been a series of four additional revolutions that transformed the production of flat glass by making, in particular, possible its *continuous* production: (i) the industrial fabrication of pure soda ash, which replaced the lower-quality product obtained from the combustion of plants; (ii) the Siemens continuous furnace, which drastically changed the melting process; (iii) the Fourcault drawn-sheet process, which was the first to provide a continuous ribbon of flat glass; and

(iv) and finally the float process, which provided a fire-polished flat glass ribbon with parallel faces of uniform thickness can now be produced with thicknesses ranging from 0.4 to 25 mm.

In spite of the success it met, however, the float process has not completely prevailed. Flat glass in effect is still produced by the cast process in the form of patterned, rolled, or textured panes. At the exit of a melter (furnace), the melt flows under a refractory gate that controls its thickness and speed before being patterned and textured on one side, while remaining smooth on the other. Today, this glass is mainly utilized in decorative, privacy

management, and solar glazing applications, for which it is often utilized instead of float glass. Patterned glass is also used as building glazing in some developing countries.

2.2 Latest Key Milestones

That the rate of innovation has kept accelerating in the last past half-century is clearly apparent in the lists of Tables 3 and 4. These items are both self-explanatory and much too numerous to be commented individually. It will rather suffice to note that five sectors are currently

Table 3 Key milestones from the 1960s to 2014 in process and product development.

Date	Change	Place
1959	Float by Pilkington (fourth revolution)	UK
1960s	Pilkington licenses in Europe and North America	Europe, USA
1970s	Batch coaters	Europe
	Tempering on horizontal furnace	World
	Structural glazing (sealed)	Europe, USA
	Step-by-step termination of sheet-glass production lines	World
	Insulating glazing in buildings as a result of energy crisis	Europe, USA
1980s	Large development of coatings (with magnetron coaters)	World
	Jumbo size becoming standard in Europe	Europe
	Bendable and temperable coatings (vacuum deposition)	USA
	Structural glazing (bolted glass)	Europe
	Extra-clear glass (beginning with the Louvre Pyramid)	Paris
1990s	End of Pilkington license: newcomers in the production of flat glass, large increase of production lines	World
	Warm edge for IG unit spacers	Europe, USA
	Oxy-fuel burners	USA
	Structural glazing (beams and large sizes)	Europe
	Hydrophobic coatings	
2000s	Easy maintenance coatings ("self-cleaning")	World
	China becoming first flat-glass producer in the world	World
	Low-iron glass for photovoltaic cells	World
	More stringent European standards instead of ASTM's	World
	Head-up displays on cars	USA
	Summer comfort becoming a focus	Sunny regions
	Passive houses – Zero Energy Building	USA, Europe
	Very large glazings (e.g. Shanghai Apple store)	Asia
	Complex shapes, glazing deformation on building included	World
	Insulating-glass units with U values of $\sim 0.5 \text{ W/m}^2\text{K}$	World
1980–2010	Thin glass for communication tools becoming new niche (some float lines producing only glass for LCD)	Asia
	Continuous price decreases in USA and Europe	USA, Europe

Table 4 Key improvements from 1962 to 2014 on coatings, tempering, laminating, and insulating glazing.

Product	Key improvements from 1962 to 2014
Float glass	- Availability of 2 mm-thick float glass in 1970 - Development of extra-clear glass from the mid-1980s (for architecture, furniture, appliances, and solar) - Development of extra-thin glass from late 1990s (for communication devices) - Larger furnaces: 1000–1300 tons per day vs. 400–500 in the 1960s - Longer furnace lifetimes: 12–18 years vs. 5 in the 1960s - Notable improvements in productivity (ton per worker unit and per year) and energy (spent per ton of saleable glass) - Usage of oxy-fuel combustion for some furnaces - Notable improvements in reduction of environmental pollution
Coated glass	- Magnetron cathodes - From batch to “on-line” process - Pyrolytic coaters dominant in the 1970s replaced by sputtering coaters from the mid-1980s (up to 10^7 m²/yr) - Temperable coatings (sputtering deposition) - Hydrophobic coatings - Low-maintenance coatings - Coatings with double and then triple silver layers - Coatings matching requirements for summer comfort - Commercial development of electrochromic coatings - Coatings for faces 1 and 4 of insulating glazings
Tempered glass	- From vertical to horizontal tempering - Notable improvement of optical properties of tempered glass - Huge productivity increase of tempering production lines - Tempering of 18 m-long glass parts in large production lines
Laminated glass	- Large demand of laminated glass for safety and security - Poly vinyl butyral (PVB) films for sound insulation - Head-up displays - Laminating of 18 m-long glass parts in large production lines - New films in addition to the extensively used PVB
Insulating glass	- Up to mid-1970s large portion of glazings are single panes - Insulating glass with single, then double sealant - Double insulating glass with low-e coating becoming standard - Argon filling becoming standard in some countries - Warm-edge technologies to reduce overall u-values - Triple insulating glass - Moving from 5.6 (single glazing) down to 0.5 W/m² °C
Glazings	- Structural glazing participating in strength of whole structure - Very large sizes - Very complex shapes - Cold bending of glazings, on building

the bigger users of flat glass (Table 5): construction (for windows and mirrors in either new or renovated buildings); car and, more generally, transportation vehicles (again for original equipment or replacement of safety

windows); appliances and furniture; solar energy (photovoltaic and concentrated power); and electronics-communications. For some or all of these sectors, insulating, tempered, laminated, or coated products have been

Table 5 Main usages of flat glass.

Business		% (volume)

Grand total		100

Table 6 Key figures about flat-glass products.

Global market	Figures
Flat glass	70 million tons per year 7000 million m ² (equivalent 4 mm)
Low-emissivity glass	450 million m ² per year
Laminated glass	300 million m ² per year
Coaters lines	Several hundreds
Tempering lines	7 000 to 10 000

Best guesses for 2014.

key factors for their markedly increasing uses of glass (Table 6).

To quote a first example, horizontal tempering eliminated the so-called tong marks of the vertical process, which has greatly facilitated the penetration of tempered products into the transportation and building markets, thanks also to an improved productivity combined with a better product quality. But a more instructive case perhaps is that of insulating glazing, which was first adopted by the transportation industry, mostly for train cars, in the 1950s and 1960s. After the energy crisis of the 1970s, the energy savings often requested through national codes induced a systematic implementation of insulating glass in the building sector. A large-scale development of coatings quickly followed in the 1980s, facilitated by the efficiency of low-emissivity coatings for energy savings (Chapter 6.7), which allowed large coaters to be made at a competitive price. At the same time, concerns for safety, security, thermal comfort, and noise reduction led to the development of insulating glazings incorporating not only

coated but also tempered and laminated glass. As a matter of fact, transportation continues to be a key driver of product development for the flat-glass industry. Although remaining a relatively minor user of flat glass in terms of volume (Table 4), it represents an important source of added value (Chapter 9.2).

Since coatings are now standard in a great many products, it is worth to remind that glass producers generally agreed in the 1960s and 1970s that pyrolytic processes would become dominant. By a twist of history, however, in the following decade the advantage shifted to sputtered coatings. Also widely used today in the building industry, temperable sputtering coatings were first developed for windscreens with a noticeable development conducted by PPG [2]. These coatings are in general less expensive, offer a wider range of features as well as often better optical and energy properties, and in addition are overcoming two weaknesses of pyrolysis processes in terms of durability and temperability. These advantages are reflected in the dramatic increase of the US sales of reflective coatings, which went from 15 000 and 270 000 m² in 1967 and 1970, respectively [3], to a current value of about 500 million m².

As for the latest developments, they concern extra-clear glass for the solar industry (mainly photovoltaics) and extra-thin glass for communication devices (telephones, tablets, and flat display panels) whose production has tremendously increased since the beginning of the 2000s.

Finally, another significant trend is that until the 1960s most of the development of new products was conducted by the producers of flat glass. Catalogs from PPG in the 1940s [4] or of Saint-Gobain [5] in the 1950s and 1960s exemplify very well the implication of flat-glass producers in product design. Today, in contrast, most of the development of new products is performed by the downstream fabricants or, for the building industry, by facade companies (Chapter 9.1). Likewise, equipment for glass processing has also been developed during that period of time by new, dedicated companies.

3 The Float-glass World

3.1 The Age of Float Glass

To assess better the current evolution of the flat-glass market, it should be noticed first that until recently the main producers were rather “old” companies funded in the nineteenth or early twentieth century to produce window and/or plate glass (Table 7). One could even state that the flat-glass industry is a very rare example of a sector where old-age companies have been able to keep dominant positions in the midst of continuous

Table 7 Foundation of some of the key flat-glass companies.

Date	Companies
1665	Saint-Gobain (France) Incorporation of its European subsidiaries in the 1980s and 1990s (Saint Roch [Belgium], Vegla [Germany], Cristaleria Espanola [Spain], Fabrica Pisana [Italy], etc.)
1826	Pilkington (UK) – Bought by NSG Group in 2006
Mid-nineteenth century	Glaverbel (Belgium) created in 1961 by merging of Glaver (founded in 1931) and Univerbel (founded in 1930), through mergings of plants/companies created in the nineteenth century. Bought by Asahi Glass Company in 1981
1848	Boussois SA (France), then Boussois Souchon-Neuvesel in 1966, then BSN in 1967. Bought by PPG Europe in 1982, then by AGC in 1998
1883	PPG (USA)
Late nineteenth century	Detag (Deutsche Tafelglas AG) merged as Flachglas with Delog (Deutsche Libbey Owens Gesellschaft für maschinelle Glasherstellung AG) funded in 1925, then bought by Pilkington in 1980
1907	Asahi Glass Company (AGC, Japan)
1918	NSG Group – Nippon Sheet Glass (Japan)
1951	PFG (South Africa), for a while the only producer of float glass in Africa
1956	China Luoyang Glass Group (China)
1962	SIV-Società Italiana Vetro (Italy), bought by Pilkington in 1995
1964	Taiwan Glass Company (Taiwan)
1965	China Glass Holdings (China)
1970	Glass processor Guardian (founded 1932, USA) entering flat-glass production
1980	Farun (China)
1984	CSG Holding (China)
1986	Muliaglass (Indonesia)
1987	Fuyao (China)
1988	Xinyi (China)
1992	Glass processor Cardinal (founded 1962, USA) entering flat-glass production
1995	Euroglas (Europe), with a first plant built in France

technological innovation, the latest of which was the float revolution. The explanation probably is that process knowledge was not widely disseminated in an industry that was in addition requiring large investments.

After seven years of research and development [6], the float process combined in 1959 the advantages of plate and sheet glass with a quality that quickly became equivalent to that of plate glass at much lower investment and production costs. Over the last 50 years, the process has thus been implemented worldwide, causing an almost total end to sheet-glass production. After its invention, Pilkington decided to license the process to other producers. The first license was signed by PPG on 27 July 1962, quickly followed by Glaverbel, Boussois, Saint-Gobain, Saint Roch and LOF and preceded by Asahi Glass Company, Nippon Sheet Glass, Ford, Mexican Vitro, Sklo Union (Czechoslovakia, at that time) and Bor (Russia). The last company to get a license in the 1960s was Central

Glass, in Japan, in February 1968. By the end of the 1960s, 20 float lines had been built but about 20 plate-glass plants were still operating. Boussois (France), for instance, closed its plant in the late 1970s after completing production of a yellow glass for the Sydney Opera.

Pilkington's policy was "not to create new flat-glass manufacturers" [7]. This is the reason why Pilkington was reluctant to provide licenses to companies that were not already making flat glass, thus excluding Guardian, which was only transforming flat glass at that time. Hence, it was believed in the 1960s that flat glass would remain a business/industry controlled by the Western world, especially because beginning float production by the new licensees could be difficult. As, for instance, reported by the New York Times in 1964, "Robinson F. Barker, vice president of Pittsburgh Plate's glass and fiber group, noted last week that the company's Cumberland float plant is just now emerging from severe start-up

difficulties,” and the Times added that “Setting up float-glass plants may also involve labor difficulties. One company that wanted to convert one of its plants to the float process was blocked by a union that objected to having a number of jobs eliminated, according to an officer of the company.” In the mid-1970s, however, float did take over sheet glass so that by the end of the decade only a few sheet plants were still in operation in North America and in Europe. In Europe, this move during the 1970s indeed caused the elimination of many jobs and, therefore, created social difficulties especially in Belgium, France, and Germany [8].

Barred from access to the technology, Guardian thus stormed into the industry by building in 1970 a factory without holding a license [7]. With the beginning of its first float line in the United States in 1970, it radically changed the landscape of the flat-glass world by focusing on a few standardized products, avoiding not only research and development but also marketing departments, making instead plant managers responsible for production and sales, and not participating in glass-maker associations or in the elaboration of industry standards. In these ways, Guardian forced the whole industry to become a low-cost business. That impact was felt very strongly in Europe, in particular, where Guardian Industries opened its first line in Luxemburg in 1981, which was the first they built abroad.

3.2 The Changing Geography of Float Glass

Until the mid-1980s, the float-glass industry was thus mainly located in Europe, United States, and Japan where the first licensees increased their number of lines. Knowledge and intellectual property, which had been controlled by Pilkington up to the early 1980s during the validity period of the patent has since been widely dispersed among many engineering companies having the capability to design, build, and start up new float lines. These companies have demonstrated the appropriate readiness to support newcomers. From the mid-1980s, they have thus facilitated the entrance of new companies which were coming mainly from the flat-glass fabrication industry, such as Cardinal or Euroglas.

In terms of number of float lines, it is interesting to note the similarities over the years between Western Europe and the United States until the late 1990s. A slight divergence then appeared, preceding the real difference that manifested itself in 2008 when Western Europe had to eliminate excess production capacity and old production sites. At last, an economic crisis marked by a deep recession had made these difficult decisions inevitable. In one respect, however, production has been fortuitously protected from foreign competition by the decision taken in the early days of the float process to produce standard

6.0 × 3.21 m sheets, to which tools have been fitted in the transformation industry. It happens that this *jumbo* size is too large to fit into containers, which are required for economic ship transportation.

In contrast, rapid industrialization in China has resulted in the sustained creation of plants, whose number has increased so quickly that it became higher than in both Europe and United States in 1997 and is now representing more than half of the worldwide total (Figure 1). As might be expected, Chinese companies are selling their glass products on the international market, mainly for automobile replacement, appliances, communication devices, or solar energy. Another significant trend is an analogous increase, but at a lower rate, of the number of float lines in Africa and the Middle East (Figure 2) where competitive advantages are provided by low costs

Figure 1 Float lines in Europe, North America, and Middle East/Africa (from 1960s to 2013).

Figure 2 Increases of the number of float lines in Europe, North America, and Middle East/Africa from 1960s to 2013.

Figure 3 Float lines as of early 2013.

for either energy or manpower. In this respect, exportation of finished products far away the production sites is made possible by low costs of transportation, by boat for long distances.

It is convenient to divide the current flat-glass world into nine regions (Figure 3), namely North America, South America, Western Europe, Eastern Europe, Russia and satellites, the Middle East and Africa, China, India, and the rest of Asia along with the Pacific region. In the Middle East/Africa, South America, and India, float glass has been absent for so long a time that the current development should keep continuing for a while. As an example, the overall flat-glass consumption is about 10 kg per person and per year worldwide, but with high values of 30 kg in several European countries that contrast with only 1 kg in India.

The flat-glass business is dominated by key players but a comparison between the data for 1988 (Table 8) and 2015 (Table 9) shows how deeply has the market changed. During the 1980s, Pilkington and PPG were the main flat-glass companies. Along with Saint-Gobain, they controlled about 40% of the business. Altogether, North America, Western Europe, and Japan had a total of 87 lines that represented 75% of the world production. In 2015, their number of float lines has slightly increased to almost 100, but this higher number barely account for

Table 8 Main producers of float glass in 1988 [9].

Company	Number of float lines	Global market share (%)
Pilkington (with LOF)	15.5	15

20% of the world capacity. Especially noteworthy are the facts that Ford completely quit flat-glass production, Pilkington and SIV are now part of NSG Group (Nippon Sheet Glass), Hankuk is integrated into Saint-Gobain, and PPG has strongly streamlined its business by selling all its operations outside North America. Although NSG Group, Asahi Glass Company (AGC), Saint-Gobain, and Guardian Industries are still dominating the business, new companies are becoming global with the potential to modify that hierarchy in the years to come.

3.3 Development and Profitability

After many good years, most flat-glass companies in Europe, North America, and Japan have suffered from a deterioration of their profitability and sales growth, if not from a production decrease. Hence, the 2008 economic crisis took place in a business environment that was already difficult. Some companies have anticipated this new era by strongly reducing their glass activities within their portfolios or even selling them completely. Good examples are BSN, which left totally the glass industry in 2004, and PPG, which was number one in the mid-1980s and later sold its flat-glass business to Mexican Vitro and its fiber-glass operations to Nippon Electric Glass (NEG) in 2017. It has now become a global leader in paints.

In this activity redistribution, an important event has been the purchase of Pilkington by NSG in 2006. Highlighting the strong influence that final users may now exert on flat-glass producers, this purchase was motivated by the need to match the overseas expansion of the Toyota car maker, one of NSG's key customers. Whereas 80% of NSG sales were in Japan before this acquisition, 80% of the sales are now made overseas. But such an increase of the market's share in a context of decreasing prices has been accompanied by a marked drop in stock value as the company's profitability strongly decreased along the way. This situation is not particular to NSG. It has been acknowledged by stock markets around the world, which have strongly devalued their assessment not only of the "pure" flat-glass companies but also of companies having a large portion of their sales in the flat-glass business in the Western world.

The contrast with African, Middle East, Chinese, and other Asian companies is striking since these have in contrast enjoyed at the same time good or even impressive growth of both production and profitability, especially in China. But the extremely strong increase in the number of Chinese plants was of course not sustainable indefinitely (Figure 1). Under governmental pressure, production lines have lately been shut down and companies – including some large ones – have even quit the business to eliminate excess production capacity. By the end of 2017, it was estimated that about only 250 plants were still operating out of a total of more than 340 built. This situation notwithstanding, Chinese flat-glass companies such as Fuyao, Kibing, or Xinyi will likely become global to lead the business and strongly contest the leadership of Western companies along with other companies (like Sisecam in Turkey) that are benefiting from a strong national market.

3.4 Some Flat-glass Economics

In the flat-glass market the deterioration of the profitability has many causes. One of them is the price of glass, which has decreased continuously (in constant currency) during the last 50 years (Figure 4). Improvements in productivity and implementation of business models focused on the low-cost production exemplified by Guardian Industries have intensified price competition all around the world during the last three decades. As a result, there has been a very striking contrast between the price of flat glass in Europe and the United States and standard price indices (e.g. construction and consumer indices in France and the United States, respectively, in Figure 5).

Actually, this trend is the continuation of a long evolution that began with the Industrial Revolution. A pioneering study has, for instance, clearly documented the continuous

decrease of production cost and selling prices of plate glass, window panes, and bottles resulting from the technical advances made between the French Revolution and the late 1980s [10]. In other words, flat-glass products are no longer rare and expensive items made by relatively few producers. They have become commodity articles made by a single process shared by all producers. Although productivity improvements and reduction of specific energy consumption have led to reduction in production costs, the profitability of Western companies has been impacted by the pressure exerted on market prices by foreign low-cost producer whose number has continuously increased, especially from the mid-1980s.

The cost of a flat-glass plant was about 50 million US\$ in the early 1970s [11] or about six times more at constant dollar in 2015. With a much improved technology, the 2014 cost was ranging from 120 to 150 or less than 100 million US\$ depending on whether the engineering was Western or Chinese. Still more striking is the contrast between the original 500 tons typically produced daily by 400 people in the 1970s and the current 800 tons made by fewer than 150 people.

Four key components mainly determine the production costs: raw materials, energy, manpower, and initial investment. Specifically, typical production costs of float glass in the Western world are split into raw materials (20%), energy (21%), labor and overheads (29%), depreciation (10%), transportation (10%), and remaining items (10%). The energy efficiency in glass furnaces can widely differ depending on size and technology and on the amount of cullet used. Along with manpower, however, energy will likely remain the main factor to be taken into account for the location of production sites.

Figure 4 Decrease of the price of clear flat glass in Western Europe from 1960 to 2014 in constant euros per ton.

Figure 5 Divergence between the prices of flat glass in Western Europe and in the United States from 1981 to 2014 and the construction price index in Paris (INSEE) and the consumer price index in the United States (Department of Labor).

Float-glass lines, nowadays, are often associated with the first level of transformation. Coatings are the prime example as low-emissivity panels have become mandatory for insulating glass in many countries, but other laminated-glass production lines or mirror production lines. In the long term, we can thus expect that 50% of the flat glass utilized by the building industry will be transformed (at the first level), which is about 40% of a float line output.

3.5 Market Trends

The float process has induced a radical change in the flat-glass industry when it introduced through its breakthrough technology a “dominant design” in the 1960s and 1970s. As already stated, spreading of the technology and know-how from the late 1980s throughout the world has transformed flat glass into a commodity product, whereas low energy and/or manpower costs have promoted a rapid development of the industry in China and the Middle East. Today, more than a dozen engineering companies are able to design, build, and operate a float line, thus offering the capabilities for any new investor to participate in the production. We are thus far from Pilkington’s original concern in the 1960s that float-glass licensing “was not to create new flat-glass manufacturers”!

As of early 2018, float glass is produced by 445 lines (running or in repair) worldwide, whereas about 200 other lines are making cast or sheet glass. A few float lines are producing borosilicate glass, generally with a tonnage lower than 100 tons per day. Most of the products sold today are either clear glass of 2–25 mm thickness or coated low-emissivity glass. But the absence of new products sold in large quantities has trapped during the last 10–15 years the industry in a spiral of low-price competition, which has much reduced the profitability of most companies located in Western world.

At the same time flat-glass secondary fabrication has been strongly modified by coatings, tempered and laminated safety products, and industrialization of insulating glass. But producers of equipment and machinery (most of them located in Europe) and some glass industry suppliers (such as logistics and transportation companies) have also been strongly impacted by the capabilities of Chinese or Asian newcomers. Several Asian suppliers or Western companies located in Asia (or producing a large portion of their equipment in Asia) are currently leading the market.

As a result, successful companies have largely left the flat-glass business when they have not just remained in some profitable niche markets such as extra-thin or electrochromic glass, or developed production outside the Western world. Another noteworthy feature is that flat glass is no longer a business almost exclusively focusing

on the building sector. Whereas the growing photovoltaic industry requires patterned products, the electronic business is requesting extra-thin glass for semiconductor substrates, touch panel displays, or fingerprint sensors (Chapter 6.10), which is made with either the float or down-draw process (Chapter 1.4). In both cases, the market is expected to grow much faster than for more traditional products.

4 Perspectives

In the early 1960s, the flat-glass industry was driven by glass producers, mainly located in developed countries. These had the required knowledge, which gave them an edge over the fabricators to which they were selling the primary material that they were not transforming themselves. Today, flat-glass production knowledge has been widely dispersed whereas the complexity with which flat glass is used in many applications also requires such a technological know-how that has made processors, façade and window companies, and flat-glass customers, in general, more powerful than glass producers.

In this context, noticeable price increases are not to be expected in an industry that remains fragmented with almost 100 producers. If South America and India should be very active markets in years to come, the situation remains uncertain in Africa and Russia whereas consolidation is expected in some regions. This is especially the case of Western Europe where the “jumbo strategy” cannot prevent large quantities of flat glass from being imported as finished fabricated products for which long-distance transportation is not much of an issue. Under these circumstances, the number of producers should not increase. Rather, one should expect a restructuring induced by the pressure exerted by extra-European producers. By comparison, the US flat-glass industry should be less strained, thanks to the lower energy costs it is now benefiting, thanks to shale gas.

Over the last 50 years [12–16], the flat-glass business has faced two major situations that were not anticipated by the inventors of float glass: a move of the production leadership out of the Western world to Asia, South America, or the Middle East, and another move of leadership – and added value – for product and process development from the glass producers to many other stakeholders involved in engineering, design, fabrication, glazing, or supply.

Most of the flat-glass products are very mature. Float glass (and most of the fabricated products) is nowadays a commodity. Market niches are very small but can remain profitable enough for companies able to exploit properly these areas. In other words, the flat-glass

industry needs new breakthrough innovations – its fifth revolution – to revive a sustainable profitability. The melting process, which is old and needs to be improved could be its target, which is why active research is being made in this field by glass companies. The current business model needs also revolution to renovate flat-glass industry practices.

9.7

Design and Operation of Glass Furnaces

Christoph Jatzwauk

F.I.C. Germany GmbH, Weiden, Germany

1 Introduction

To a large extent, the history of glassmaking is that of melting furnaces. Throughout the ages, the course of the reactions between the raw materials largely determined quality as well as production volumes and cost. Thanks to the new science of thermodynamics, the major improvements progressively brought in the nineteenth century resulted in the invention of the *regenerative tank* furnace (Chapter 10.9). Not only were then melting temperatures higher and more uniform, but heat hitherto wasted was recovered while continuous instead of batch melting ensured the much higher throughputs, more durable equipment, and lower labor costs that have since then sustained the expansion of the glass industry.

Modern furnaces are typically from 8 to 40 m long, 5–15 m wide, and hold enough glass over typical depths of 0.9–1.4 m to ensure a daily production ranging from 20 to 700 tons with extreme pulls exceeding 1000 tons for a total investment cost ranging from about 2 to 15 M€ as of 2019. These furnaces of course differ from those designed by the Siemens brothers and other nineteenth-century engineers, but the basic goals involved have remained the same, namely to save as much energy as possible and to deliver continuously at the best cost a homogeneous melt ready to be shaped. The main changes have been: (i) the switch from coal to natural gas, heavy oil, or electricity as a heating source; (ii) the nature of the refractories used for the tank, combustion space, and preheating chambers [1], which have much benefited from advances in the technology of ceramics and other relevant materials; (iii) the precise tailoring of a furnace in terms of the energy sources available, targeted pull rate

(and possibly intended variations), kind of production and raw materials used, cullet included (Chapter 9.9); (iv) the manner in which the geometry of the tank and its temperature distribution are designed to optimize melt homogenization and fining by the currents generated by the free convection caused by temperature and density differences, the exerted pull, and possible bubbling and electrical boosting; (v) and increasingly strict environmental regulations in terms of emissions of CO₂ and pollutants, particular emphasis being put on sulfur and especially nitrogen oxides (SO₂, SO₃, NO, NO₂, N₂O, and their derivatives), which are generically denoted by SO_x and NO_x, respectively.

Like in any complex industrial production, changes in the various chemical and physical factors involved may have opposing effects in the technical optimization of the overall process as well as on fabrication costs. Compromises have thus to be found, which is why a given furnace will be adequate for a given use at some place but not for others elsewhere. This is also why a new furnace still requires much experience from its designer in spite of the wealth of information that can now gathered a priori from computer simulations of the whole melting operations (Chapters 1.7 and 9.8).

To review these various features in this chapter, a brief overview of furnaces will first be provided through their *hearts* (the melters) and *lungs* (the regenerators) and of the five main types of heating systems. The fusion process itself will not be addressed because it has already been described in Chapter 1.3. A more detailed description of the tank and superstructure of melters, of the regenerators, and of their ancillary equipment will then be given, interest being paid to the nature of the refractory materials used whose resistance to corrosion and thermal shock are critical in any respect [2]. Finally, some general considerations about furnace design will be reviewed before the issue of pollutants emitted such as NO_x will also be

Shelby, NC, USA

considered in view of the ever stricter nature of environmental regulations.

In contrast to forming processes, which are mainly determined by the kind of production (e.g. float process for window glass), melting of the batch can be made with different types of furnaces for the same production. More than elsewhere in the Encyclopedia, economic factors will thus form the backdrop to the present chapter. From this standpoint, a basic figure is the specific load, which is the amount of glass daily produced by surface area of the melter: the production (in tons per day, tpd) is then derived at once from it and the melter surface. As illustrated by the fact that melting alone represents 60–70% of the overall energy spent in glass production [3], the energy efficiency is another fundamental notion to which another chapter is devoted (Chapter 9.8). In view of the introductory nature of the present account, interested readers are referred to standard treatises for more detailed descriptions (e.g. [4]).

2 The Furnace Families

2.1 Common Features

Glassmaking furnaces are generally not specific to a given type of production because their operations depend on so many factors that they can be optimized in different ways and adapted to particular features of the glass produced (e.g. fluor volatilization in opal glass, low thermal expansion of borosilicates, high Fe content of rock wool). In contrast, their sizes depend on the subsequent forming process because they are mainly determined by the desired pull rate. This is the obvious reason why the biggest are those designed and built for float glass (Chapter 1.4).

The most conspicuous part of a furnace is the melting tank (Figure 1). It is fed with the raw materials coming from the outside batch silo at the *doghouse* whose design depends on furnace type. The batch is heated up to typically 1500 °C at the *melting end* on one side of the tank, which can include a dam wall as well as bubbling and electrical-boosting systems to achieve complete melting. Sometimes in a *refining bank* that is shallower and hotter than the other parts of the melter, the distinct steps of primary and secondary fining then follow to yield a chemically homogeneous melt bearing as few defects as possible at the *working end* on the opposite side of the tank (Chapter 1.3). There, the melt is delivered through the *waist* (or *neck*) for float glass (Chapter 1.4), the *throat* for container glass (Chapter 1.5), or by overflow for rock wool (Chapter 9.13). Depending on the kind of furnace used, the melt is then *conditioned* on its way to the forming devices so as to reach the appropriate homogeneous

temperatures and viscosities required by the process. To achieve the temperature reduction of 150 °C for example needed for container production, the glass is cooled at the center of the feeder canal but need to be heated at the sides where cooling would be too fast.

The volume of the space left above the tank up to the *crown* depends on the heating system, being small for electric melting but large to accommodate the burners of a combustion chamber. Whenever flue gases are produced, furnaces include either *regenerators* or *recuperators*, which are of the same types as those used in other high-temperature processes [3]. As originally designed in the nineteenth century, regenerators transfer discontinuously heat that would be lost to the chimney to the combustion gases before they reach the burners (Chapter 10.9). They consist of two or of an even number of chambers designed to store as much heat as possible in a checkwork of refractory bricks (a *checker*, for short). In one chamber, the flue gas typically cools from 1450 to 600–400 °C while the combustion air may heat up to a maximum temperature of typically 1100–1300 °C in the other chamber; the additional heat thus delivered to the combustion space increases the heat set free in the furnace beyond the level reached by the net calorific value of the fuel alone (Chapter 9.8). Every 20–30 minutes, depending on the *thermal load* of the furnace, the flows of both fluids alternate in less than one minute during which firing stops. With recuperators, heat is in contrast exchanged continuously between the flue gas and combustion air through a co- or counter-current. What then matters is not the capacity of the exchange medium to store heat but to transport it rapidly. These devices are often termed *radiative* recuperators because of the nature of heat transfer from the hot flue gas; the colder combustion air is in contrast heated up by convection only, up to 750 °C with the most efficient systems. Thin-walled materials are required for the exchange. For mechanical reasons, high-temperature steels must be selected but they severely limit the entry temperatures of the flue gas. Although recuperators are theoretically more efficient than regenerators, they do not reach the efficiencies of regenerators in glass furnaces.

Sometimes with the help of electrical boosters, the batch is most frequently melted by the heat radiated directly by the flames (adiabatic temperatures of about 2700 and 3000 °C for air-fuel and oxy-fuel combustion, respectively; technical temperatures of 1650–1800 °C for both cases) and indirectly by the crown at typically 1600 °C (Chapter 9.8). Since the 1960s, burners are fueled with natural gas (methane, CH₄) or preheated heavy oil atomized in a nozzle by means of pressure or compressed air or methane. Solid fuels are mainly used in China where petcoke, a residue from petrochemistry, is transported to burners by means of propellant air.

2.2 End-Fired Regenerative Furnaces

Because they are economically efficient for various kinds of production (Table 1), end-fired furnaces are at present the most common. They have two ports equipped with 2–4 burners each and located on a single side next to the regenerator (Figure 1a). The flames from one port develop over the whole length of the furnace and turn 180° back toward the other port where the flue gas is extracted. This U shape gives them a long residence time. Their advantages are a highly preheated combustion air and a relatively low energy consumption. As a result, they have a high thermal and overall energy utilization efficiency, which translates into a high production efficiency and a high specific load. Owing to this efficiency, they are becoming extensively used to produce container glass. As a disadvantage, they allow for a limited control of energy distribution along the longitudinal axis of the furnace, which results in some limitations to achieve an ultimately high glass quality. Their investments costs are relatively high, however, as are their NO_x emissions, and they require maintenance work for chamber cleaning and fixing expansion joint areas for furnaces larger than 10 m.

2.3 Cross-Fired Regenerative Furnaces

By far the biggest ones, cross-fired furnaces are mostly dedicated to float glass (Table 1). From 4 to 8 burner ports are placed on two opposite sides next to the regenerators (Figure 1b), so that the temperature profiles along the longitudinal axis of the furnace can be tuned to obtain for primary fining a hot spot of a given size at the right place. This results in an enhanced control of glass quality, an important issue since the presence of a single tiny seed may lead to the rejection of a large flat glass sheet. Cross-fired regenerative furnaces are less energy efficient and reach lower specific loads than end-fired furnaces. The arrangement of the regenerators makes them more

expensive to build. And a latent problem in float furnaces is the clogging of the first chamber sections of their regenerators by the dust carried by the flue gas.

2.4 Recuperative Furnaces

Float glass is the main product not melted in the other kinds of furnaces (Table 2). In *recuperative* furnaces (Figure 2a), firing has the advantage to be continuous. From 5 to 15 burners are placed on both sides so that temperature profiles can be tuned finely. Other advantages are low NO_x emissions for container glass, a clean combustion air, and low investment costs due to relatively low air preheating, with the resulting disadvantage of high energy consumption and, thus, of lower furnace efficiency.

2.5 Oxyfuel Furnaces

Dating from the 1990s, oxyfuel furnaces (Figure 2b) are recent developments. The oxygen content of the combustion gas is increased to 91–98 vol % to avoid the energy wasted for heating the 78% nitrogen (and 1% argon) of the air up to the combustion temperature and reducing at the same time NO_x emissions and the volume of flue gas produced. The oxygen is generated on site either cryogenically or via pressure swing absorption by zeolite molecular sieves or, alternatively, is delivered as a liquid in tanks or by a pipeline from the production site. The efficiency is much higher for oxyfuel than for other fired furnaces so that the specific load is also higher. A very good adjustment of the temperature profile over the furnace axis is again possible, but condensates are generated by the wet waste gases. Oxygen generation not only means very high operating costs, however, but often difficulties for suppliers to backup the availability of liquid oxygen beyond a certain tonnage. In Europe and most parts of the world, oxyfuel furnaces are profitable only if electricity costs are less than

Table 1 End- and cross-fired regenerative furnaces.

0.035 €/kWh (2018 value). They are nonetheless drawing more interest for environmental reasons especially in the United States. An interesting development has been brought to the market by Praxair Co. with the OPTI-MELT™ system, which uses a regenerator for preheating a mixture of flue and natural gases to produce a synthetic gas that is then fired with oxygen. By this process, part of the thermal energy of the waste gas is converted into chemical energy to enhance efficiency.

Oxyfuel furnaces are by definition especially advantageous if higher melting temperatures are required (e.g. for cover glass above 1700 °C) and for the production

of glass of a very high quality. Cases in point are continuous fibers for which even microscale defects (i.e. inclusions or local composition variations) cause breakage of the thread in the drawing machine. To ensure excellent quality, however, boosting and/or bubbling systems as well as different wall types and even a refining bank can be needed. When float glass is made with two production lines, an all-oxyfuel furnace also makes sense because the waste nitrogen is recycled in the atmosphere of the two tin baths (Chapter 1.4) while energy consumption with 100% oxygen may be reduced by 25 % and emissions of CO₂, SO₂, and NO_x by 15, 38, and 83 %, respectively.

2.6 All-Electric Furnaces

As indicated by their names, all-electric furnaces (Figure 2c) melt the batch with intense electric currents delivered by arrays of electrodes immersed in the molten glass [5–7]. Earlier, electrodes were made of graphite but they suffered from short operation times of 1–5 months and current densities of 0.3 A/cm² only. Today, currents of typically 200 V and 4000 A per array are most frequently delivered by electrodes made of molybdenum, which stands out by its high melting point of about 2600 °C and its high thermal-shock resistance ensured by a low thermal expansion but gets highly corroded under strongly oxidizing conditions. Molybdenum is available in diameters from 30 to 150 mm and lengths up to 2.5 m. The electrodes are operated at voltages of 200 V, 50 Hz AC, and reach current densities of about 1.5 A/cm² corresponding to currents of 1–3 kA per electrode array.

For high-purity optical glasses, Pt or Pt-Rh electrodes are used at current densities of up to 2 A/cm². They have excellent corrosion stability in oxidizing melts but are sensitive to reducing conditions and must be operated at AC frequencies of typically 1–10 kHz below which metal dispersion into the melt would take place. Other electrode materials like SnO₂ (0.5–0.7 A/cm²), W, or MoZr₂ are used in special cases only.

Electrodes are also widely used for additional energy input in fossil fuel-fired furnaces. This is obviously advantageous in terms of NO_x emissions. For container glass, however, fully electric melting of colored glass is not possible when strong ion absorption in the infrared (Chapter 6.1) makes heat transfer inefficient within the bath. Very expensive backup systems for uninterruptible power supply are in addition needed and the efficiency loss caused by high-voltage lines from the power station is often not considered, which is to be viewed critically from an environmental standpoint.

3 Melter

3.1 Alumina–Zirconia–Silica Refractories

The lifetime of a furnace is determined by the wear of its refractories. A major advance in furnace design thus resulted from the invention of electrofused cast alumina–silica materials in the 1920s (Chapter 10.9), which are highly refractory and have a porosity as low as 1–2% to reduce the interface reaction with the melt to a maximum extent. In addition, the material must have good mechanical properties at the working temperatures and be in particular resistant to thermal shock. Nowadays these constraints are best satisfied with electrofused

alumina–zirconia–silica (AZS) where the ZrO₂ component ensures a unique combination of strength, fracture toughness, high ionic conductivity, and low thermal conductivity [8]. In glass melting, zirconia is also important because of its low reactivity with silicates and the high temperature of 1800 °C of the eutectic of the system Al₂O₃–ZrO₂–SiO₂. Commercial compositions are typically close to that of this eutectic with about 40 wt % Al₂O₃, 40 % ZrO₂, and 20 % SiO₂.

It was initially thought that lower ZrO₂ contents would be preferable because of the stresses induced by the volume changes of the monoclinic–tetragonal phase transition of ZrO₂ at 1000–1200 °C on heating and 1000–800 °C on cooling [8]. The opposite has found to be true, however, because the microstructure of these refractories is the key to their properties. Upon cooling of the electrofused melt, baddeleyite (ZrO₂) usually forms first but eutectic precipitation rapidly takes place in the form of closely entangled skeletal zirconia and corundum (Al₂O₃) laths. These find themselves embedded in 10–20 vol % of a Zr-bearing aluminosilicate glass [1, 9], which is soft enough at the temperatures of the zirconia phase transition to accommodate the stresses it produces. The baddeleyite crystals have a morphology that makes it difficult to expel them from the material upon corrosion and, on the contrary, help to keep the corrosion products in place. Upon fabrication, elements like sodium are added as fluxes whereas oxygen is bubbled through the AZS melt to oxidize any carbon from the electrodes and other species that could react with the molten glass.

The corrosion rate of ASZ does depend on composition, however, being much faster for calcium aluminosilicates than for soda-lime silicates [10]. In the latter case, corrosion begins by sodium diffusion into the amorphous phase of the refractory [9], first causing corundum dissolution and, in contrast, baddeleyite growth due to Zr oversaturation of the newly alkali-enriched phase [11]. At the same time that the microstructure of the refractory keeps degraded in the bulk by other phase changes, the sodium aluminosilicate phase exudes at the surface, leaving cavities at the waterline of the tank that are enlarged by the mechanical wear of the moving molten batch [12]. The corrosion rates are lower for larger checker volumes and they also depend on the sizes of the furnace and melting area, cullet fraction, specific load, boosting, and numbers of job changes. The yearly wear rate typically ranges from 1 to 3 %, but examples of 120 m² furnaces associated with large regenerators of 3.3 m³/m² show that rates as low as about 0.4 % during the first three years of operation can be achieved for 5 % boosting and a cullet fraction of about 20 %. The rates of 0.8–1.1 % observed during the following eight years confirmed that slightly higher investment costs do pay off.

For melting C and E glass (Chapter 1.6), basalt (Chapter 9.3), and other special glasses, Cr-based refractories are alternatively used. With a melting point of 2435 °C, Cr_2O_3 is significantly more resistant to corrosion in silicate glasses than AZS but is much more expensive. Whereas AZS costs from 4000 €/t for bottoms and 8000 €/t for walls and throats, respectively, the price of isostatically pressed chromium oxide is 30,000 and 40,000 €/t for palisades and throats, respectively.

3.2 Tank

The melter is divided into the tank in contact with the glass and the superstructure. In the former, the depth of the glass generally ranges from 900 to 1400 mm (Table 3). The melting and refining ends may be separated by a single- or double-row *dam* or *weir wall* to let the colder glass rise from the bottom for being heated and fined (Figure 3). By enhancing convection and avoiding shortcuts in the flow, one increases output, ensures the required quality, or improves production flexibility and energy consumption. Such a dam can be made of 41% ZrO_2 AZS or of a dense Cr-based refractory and

may need to firmly “anchored” in the furnace bottom by a specially shaped block.

The bottom of the tank consists of refractory layers whose number, nature, and thicknesses are determined by the operating conditions. It typically consists of five layers with different functions.

The first upper two layers make up the *paving*. These are plates of fuse-cast ASZ or, for very corrosive melts without specific requirement for glass color, Al_2O_3 – Cr_2O_3 plates of about 120 mm thickness paved in offset stacking (i.e. such that the joints of the lower layer are covered by the upper plates). It is of utmost importance that no bubbles are generated at the brick-melt interface. Below the paving, a layer of zircon ramming mass, about 80 mm thick, absorbs the tensions caused by the thermal expansion of the paving during heating-up. It also effectively stops any metal drops and small amounts of glass melt that locally penetrate the paving. The mechanical support is secured by the forth layer (200 mm) made of material from the sillimanite (Al_2SiO_5) family. This layer has to carry the load of the glass melt and the upper refractory layers, which amount to 3.5–4.5 t/m² depending on the depth of the glass bath or even 8 t/m² for a deep fining zone. It is directly connected to the steel framework supporting the entire construction. The fifth layer is made of light chamotte bricks. Its function is the thermal insulation of the bottom; its thickness is chosen according to the desired function.

Because the refining end can be as deep as 2800 mm for color container-glass furnaces, its design must prevent the melting part from pushing toward the throat whereas bottom electrodes may be installed next to and also often in front of the throat. The bottom refractories of the refining end are usually the same as those of the melting part, but some layers can be omitted to comply with building requirements or to increase heat losses for glass preconditioning. The entire melting and refining parts are edged by a basin consisting of a combination of 200–300 mm

thick soldier blocks, arranged without any mortar, between which empty spaces of about 2 mm must be left to let the blocks become tightly packed at 1550 °C through thermal expansion. To account for thermal expansion mismatch between layers, a special arrangement of steel bracing allow all bottoms layers, the wall and the palisades to be loosened upon heating up while ensuring that no joints remain open.

3.3 Additional Tools: Bubblers and Boosters

For colored glass, a dam can lead in front of the wall to *dead* areas without flow so that the effective bath volume is reduced. For sustaining flow in the entire volume of the melting end, a first means is to blow from the bottom large bubbles of air, oxygen, or nitrogen at a certain distance before the dam wall through a specific number of nozzles made of MoSi₂ or ceramics (sometimes sheathed with a Pt alloy), which may be water-cooled to be protected from corrosion. One then increases the specific load of the furnace by causing colder melt present at the bottom to rise toward the surface through local convection currents created around the paths of the bubbles, but at the price of an increased energy consumption.

Depending on color and cullet fraction, bottom electrode blocks are in addition often displayed according to well-defined patterns in numbers that depend on furnace size and required output. The initial bottom and the soldier blocks of the melting end can be specially shaped to enable the installation of such bubbling or boosting systems at a later stage. Boosting can be permanent or required only for certain tonnages in ways that depend on bath depth and electrode arrangement. It has obviously an important impact on the energy efficiency of the furnace. The maximum specific electrical energy to be applied to avoid premature corrosion in a bottom-boosting system is known empirically. For container glass, intensities of 1.5 A/cm² are briefly exceeded in some cases whereas the maximum is 0.8 A/cm² with molybdenum electrodes for other glass types. Depending on size, there may be several electrical circuits. Some 175 m² end-fired furnaces designed for the Indian market have, for example, an installed boosting capacity of about 6 MW, divided into four different circuits.

3.4 Superstructure

The superstructure of the melting furnace consists of walls (port gable, breast, and throat) capped with the crown. The walls have peep holes for inspection of the melting end (Figure 4) and openings to measure the furnace pressure as well as the temperature of the inner crown with lateral optical thermocouples. Likewise, the

Figure 4 A view over a wool-glass bath through the peep hole of the melter. Source: Photo Isover Saint-Gobain, courtesy Jean-Luc Bernard.

flame and the batch distribution are inspected with a camera – or two, for the large float furnaces – installed in the throat gable, which could be combined with an infrared unit for additional temperature measurements.

Nowadays, the superstructure is mechanically independent of the glass-contact section, thanks to the *tuckstone* on which its walls rest, whose weight is exerted on the steel bracing support. A 40 mm joint filled with fiber wool separates the tuckstone nose from the soldier blocks, which can thus freely expand upon heating before being shut closed manually from the outside by a ramming mass or metal oxide–metal welding. Fused-cast AZS bricks backed up by high-alumina refractory layers of the required thicknesses are used to obtain an appropriate temperature profile within the walls. For parts in contact with flames, ceramic-bonded AZS bricks make it possible to use 2 × 1 m ZEBRA™ blocks and to prevent the so-called glassy phase from being exuded and causing glass defects.

As for the crown, it is either freely suspended or rests directly on the side walls with which joints have to be sealed after heating but before tank filling. Depending on the total length, it is split into segments about 4000 mm long. It is made of mullite (3Al₂O₃·2SiO₂) layers, or of AZS for certain glass types, which is most generally lined with silica, especially of a “lime-free” kind to sustain temperatures as high as about 1640 °C. Thermocouples are installed either directly or indirectly. It is because they always represent a weak point over the service life that the aforementioned optical means are paid much interest.

3.5 Operating Features

3.5.1 Batch Loading

As far as possible any contact between the various refractories of the melter and the reactive batch should be avoided to prevent premature damage. For float glass furnaces, pusher-type planar chargers are used to supply the batch as a carpet onto the bath. For container glass, batch piles are often pushed into the furnace by tappets that can forward the batch either horizontally or at different angles. But the most common type of chargers is a chute whose vibration intensity determines how much batch and cullet are supplied. Water-cooled paddles are often installed as an oscillating system in front of such vibrating chutes, which plunge into the glass bath and thus divide the batch into piles that melt much more easily. If the upper part of the charger can be pivoted, then the batch can be directed toward the furnace, which is essential not only for end-fired furnaces having a single doghouse, but also for elongated furnaces (length-width ratio >1.75) with a load higher than 3.3 t/d.m^2 . If the batch piles cannot be divided in distinct parts, *crocodiles* form as snake-like batch piles that melt very slowly and mostly settle on the opposite furnace side, causing high corrosion in the flux line area. Such an irregular settling of the batch translates into unstable temperatures in the superstructure and can influence NO_x values. Screw chargers are also used, but for special glasses for which they “only” deposit the batch onto the surface. An advantage is to allow for tight sealing of the doghouse, but batch materials must not abrade the screw to avoid defects and discoloration especially in low-iron and special glasses.

3.5.2 Monitoring

Measuring and control technologies are of vital importance for running furnaces. The furnace pressure must be monitored near the glass bath to limit (i) any flame

influence, which could cause spurious signal perturbations, and then improper pressure regulation; (ii) glass-level fluctuations and in the end production losses due to weight fluctuations of the gob especially with high-output IS machines for lightweight container glass (Chapter 1.5). The glass level in the tank and partial pressures of O_2 , CO , etc., are also monitored.

Temperatures must also be continuously measured with thermocouples in the regenerator section, furnace superstructure, and glass contact zone for ensuring production stability in every respect. Two different process-control systems are in fact used. The most straightforward would be to regulate the fuel consumption to make sure that the temperature measured at a given place remains equal to the set point appropriate to the batch composition. Because thermocouples age with time, however, the refractories could be massively damaged and the crown totally damaged if a spurious temperature drift were not detected. In the second process, therefore, one rather checks the fuel consumption and considers the temperatures measured in the superstructure only as indicators. In both cases, however, it is very helpful to make detailed pyrometric measurements to detect possible thermocouple aging and to use reliable “EXPERT” systems to compile and analyze continuously all measurements to identify any problem and fix it immediately for stabilizing the production process.

4 Heat Management

4.1 Burners

The design and arrangement of burners are really important issues. To control both flame size and shape, burners are equipped with an inner and an outer nozzle fed

Figure 5 The two nozzle of gas burners (a) and the resulting gas flow (b). Source: Courtesy FlammaTec

by main and secondary fuel gas streams, respectively (Figure 5). In a simple design, the incoming gas stream is divided manually by means of a valve directly attached to the burner. With a more advanced, but expensive method of fuel regulation, the relative positions of both nozzles can be varied, too, to produce very specific flame geometries for primary NO_x control. To stabilize the flames or reduce pollutant emissions, other tools can be installed in the superstructures of the melter. These include oxy-enrichment of the combustion air by pure oxygen, combustion with staged burners, and systems such as ggENOX™, which oppose the flow of flue gas to increase its recirculation and, thus, its residence time.

4.2 Regenerators

The refractories of the regenerators are a driver of the overall investment costs because they represent about 70 % of the total mass of a furnace. As illustrated by an end-fired regenerative furnace (Figure 6), so many parts should be considered for a detailed description of a regenerator that only a few essential elements will be mentioned here. Most important in this respect is the *port neck*, which connects the regenerator to the melter. On the one hand, the differential expansion, especially vertically, of the regenerator and melting end must be adjusted so as to avoid any unintentional shift and keep the expansion joints in the entire sections

Figure 6 Individual components of an end-fired regenerative furnace.

E. Feeder: different components not explained in detail.

perfectly closed. On the other hand, the port neck must ensure an optimum energy supply to the glass bath and also, in combination with burner arrangements, low NO_x values, while preventing critical corrosion of the breastwall and/or crown in the melting end. On the furnace side, these functions are exerted by the *port mouth*. Its bottom is generally lined with AZS and its other parts also of AZS material for glass containers or of other materials such as mullite or magnesia (actually made up of 80% MgO along with Mg aluminates, silicates, ferrites, etc.), which are outwardly insulated with differently graded materials.

On the regenerator side, the entrance bears the highest load because of the contrasting temperature conditions of the firing and flue gas phases and of chemical attack from fuel and batch vaporization. The regenerator head with its special volume ensures that the flue gas is well distributed into the checkers to store in 20–30 minutes a maximum of heat to be then transmitted to the combustion air. The same applies to cross-fired furnaces, with the difference that the flue gas leaves the superstructure on the opposite side and then preheats the opposite regenerator side. This arrangement does not apply to recuperative furnaces and oxyfuel furnaces with continuous and permanent firing from either side.

In the overall stability of the regenerator walls, expansion in both horizontal vertical directions is considered. The lower part of the regenerator, the *downport*, has openings for cleaning. Its *ridger arches* and then *spanner tiles* and transition layers are mainly made of fireclay bricks; sillimanite, high-quality sillimanite, or even mullite or silica then become employed when the flue-gas and combustion-air profiles reach a temperature of about 800 °C. The checker rests on this basis. Its elements have been designed in various ways to optimize gas flow. The most common are the chimney-block and cruciform checkers, whereas straight basket-weave and staggered grid packing are also alternatively used outside Europe. Not only are higher-quality refractories successively implemented but they also must be compatible with the fuel used and the batch composition, but their thickness increases up to the regenerator head whose target wall is disproportionately stressed in comparison with the port neck.

The reversing unit separates the combustion-air from the flue-gas flow. Combustion air is sucked up via a fan and blown in via the air-connecting box of the reversing unit to pass through the downpart regenerator, to be preheated in the checkers, and eventually to reach the regenerator head from where it enters the melting end through the port neck. As for the fuel, it is brought through the port neck bottom by a special lance, located laterally in the port mouth or beneath the port-apron block, to the burner blocks where the flames form and are shaped.

Since the entire system is hydraulically connected, it is of vital importance for end-fired and cross-fired furnaces that the reversing process be smooth and gentle not to cause level fluctuations at the melting end, which would propagate downstream. In end- and cross-fired furnaces, one can reduce the impact on the glass level by igniting burners and burner ports at staggered intervals. In end-fired furnaces, the U-shaped flame is deflected at the throat gable wall and then passes through the other port neck.

4.3 Recuperators

Ceramic systems are often operated with a *falling* flue-gas flow. When they are brand new, heat from the flue gas exchanged in cross flow via shaped ceramic bricks brings combustion air to 1000–1150 °C, a range that almost reaches that of regenerators. When the system ages, however, complete separation between the air and flue-gas flows is no longer achieved so that preheating temperatures decrease and more air must be supplied to ensure the stoichiometry of the combustion reaction. In addition, dust deposits from the batch in the upper layers corrode their ceramic bricks and minimize heat exchange. Brief interruptions of the combustion-air flow due to power failures also affect the tightness of the systems because of overheats in some parts of the recuperator and then of the formation of cracks and joints upon gentle restart after shutdown.

Metal recuperators thus tend to be preferred because of the intrinsic fragility of ceramic systems. They can be designed with rising as well as with falling flue-gas flow. The former design is frequently chosen when condensates and re-sublimates form since gravitation bring the solid particulates back into the hot section from where they can be removed, when almost liquid, via special openings in the recuperator bottom. This design is also often used when a lack of emission requirements allows the flue gas to be discharged freely. In this case, the control of the furnace-pressure dampening and the chimney installed behind the recuperator are used permanently, and not solely in case of emergency as with other systems. Falling flue-gas is in contrast frequent to integrate an existing channel that leads through a filter to the chimney. The disadvantage is that condensates and re-sublimates forming upon cooling of the flue gas can accumulate or deposit on recuperator parts, reducing heat exchange, lowering the preheating temperature, and eventually causing slow plugs up and furnace problems.

Metal recuperators are basically of two kinds, which can be combined in different ways to increase preheating temperatures from 650 to 750 or even 800 °C, the highest working temperatures of current alloys. Higher temperatures could in principle be reached with ceramic

compensators before the flue gas temperature has reached a range at which steel may then be used. The unsolved problem is that ceramic refractories should be thin-walled to be good heat exchangers, which is problematic for brittle materials and would result in short service lifetime.

With *double shell* or *gap* recuperators, heat exchange by radiation and convection takes place between two concentric stainless-steel shells insulated with ceramic fiber and rock wool, the flue gas and combustion flowing directly or counterflowing in the inner and outer shells, respectively. To increase exchange surface, and thus heat flow, baffles or checker plates are fitted to the inner tube. These recuperators can also be used for preheating natural gas or pure oxygen up to certain temperatures. For lead glasses, preheating temperatures are generally limited to 450 °C, otherwise the recuperator would be rapidly destroyed by Pb-bearing flue gases. The *tube-bundle* recuperator whereby combustion air flows in small tubes included in the big one of flue gas is by far more expensive but can be used in higher temperature ranges without any problem. The bundle of tubes is often inserted in a part lined with refractories. Also here the tubes are corrugated to increase the surface, so a larger heat-exchanging surface for the air to be preheated is created.

Safety systems are an important aspect for all recuperators because overheating often cause distortions and cracks, which result in leaks through which the flue gas and combustion air mix. In addition, the air fan must have a permanent power supply because any interruption of the flow of the combustion air must be avoided. Another safety device is a flap opening automatically in case of power failure, through which cold air is sucked into the system to protect the inner shell. This system can be combined with a separate cooling or injector fan to achieve better cooling. Depending on the design of the entire system and on working temperatures, the combustion air could become too hot. The inlet section can thus be cooled, and the air that is not required for combustion and has already been preheated is simply “blown off.”

4.4 Flue-Gas Channels

The waste gases are evacuated by channels at about 600–300 °C to the chimney after having given away most of their heat to a recuperator and/or a flue-gas purification system. To prevent concrete from overheating, cooling slots are frequently installed underneath the channel. Different grades of refractories are selected as a function of the predefined temperature of the flue gas, of possible corrosion, and also of the local economic conditions. For fast, solid, and tight construction, the side walls and the arches of the channels should be completely or at least partially cast especially for complicated and angular

designs. But prefabricated parts are much helpful to reduce the erection time whereas traditional brickwork is generally chosen along with adequate thermal insulation in countries where labor cost is low.

Not surprisingly, recuperative and oxyfuel furnaces require fewer devices to be installed in the channels compared with regenerative furnaces. Only the outgoing pipes for the heat exchanger and the waste heat-recovery systems or filters are taken into consideration, sometimes along with the furnace pressure-regulation device. This happens when this pressure is not adjusted via a kind of induced draft or by means of cold injector air that expands in the hot flue gas current and, thus, creates a kind of counterpressure.

If flue gas is very wet and the potential for condensation is high, temperatures up to the filters and chimneys must be carefully checked in view of potential condensates. Within given temperature ranges, special sections and areas are inserted in the channels to reduce the flue-gas velocity so as to facilitate dropping of the particles. In oxy-fuel furnaces, a widened flue-gas channel often serves as a quenching chamber to cool down the flue gas with water or cold air. A kind of “pre-cleaning” of the flue gas is then facilitated if this quenching takes place at the right speed and temperature.

In regenerators, flue-gas reversal stations must be carefully designed. Because they are close to the regenerators, they are made with gray cast-iron slides that must run smoothly on rails to keep sealing tight. If not, ingress of the so-called *false air* would be problematic as it would, for instance, adversely affect reduction of NO_x emissions. Because of temperature changes made every 20 minutes, the stresses induced enable very sturdy connections between the stations and channels to avoid any false-air ingress. In modern reversal stations, a simple mechanical safety device ensures that the flue gas is released on one side at the same time that the combustion air is introduced on the other. For big cross-fired furnaces, it may be preferable to have several smaller reversing stations instead of a big one for better handling and more targeted distribution of combustion air. This applies specially to float furnaces for which up to eight sectional regenerator chambers allow the energy input and the temperature distribution along the longitudinal furnace axis to be accurately controlled. Regenerators without internal separation walls are less expensive and easier to operate, but also less effective in the control of longitudinal energy input.

In end-fired furnaces, a new concept has prevailed since the 1990s. It was designed fortuitously – and then found more efficient – when some local configuration prevented the usual one from being implemented. It consists in letting the flue-gas channel pass beneath the melter to reach the port neck. The disadvantage of equipment

damaged in case of a glass leakage is minimized by an appropriate structure for the bottom of the melting end. As for the advantage, it is a more even and continuous flow that results in a reduced energy consumption and slower furnace aging. With units getting bigger and bigger, end-fired furnaces now benefit from a similar solution whereby three or four sub-channels are used depending on furnace size. A targeted “regulation” of the flow through the diverse parts of the regenerator is facilitated in this manner because the temperature profile in the regenerator can be controlled during the firing phase, thanks to the several ways in which the combustion air can be introduced. With such subcanals, however, ways should be carefully designed to clean the regenerator bottom from condensates and dusts.

5 Furnace Design

5.1 General Considerations

Depending on local situation, the first step consists in determining the furnace type and size and the energy to be used that would yield the best operating results as a function of the costs of energy and raw materials as they may be guessed over periods of time reaching now from 15 to 20 years. Although electrical boosting should in principle be kept as low as possible, it is more advantageous when electricity prices are lower near nuclear power stations or hydropower plants. By making the superstructure taller, one can increase the energy input in such a way that the specific load increases to a certain extent but the gain has to be balanced against higher construction and refractory costs and also higher heat losses. The issue is again considered whenever additional investments or repairs are to be made. In India, where labor and refractory costs are low compared with those of gas or oil, large regenerators are built to reduce energy consumption as much as possible. In Europe, the solution is sought more pragmatically to come close to the optimum in every respect.

Market conditions are in addition relevant for container glass. In the United States, very big Triple-Gob or Quad-Gob IS machines are often used to produce the same kind of container for more than half a year with a constant, low cullet fraction. Tanks seldom need a big wall; they are usually a little bit deeper and their specific loading capacity is a little higher but they require a well-designed working end with ample volume for good control of glass conditioning. In Europe, the available cullet fluctuates daily on the market so that its fraction incorporated varies accordingly. Melters must then be very flexible whereas Quad-gob IS machines are not common and used only for small items up to about 150 g. These melters

therefore require various tools. A wall is an important element whereas the refining end has to accommodate tonnage leaps during production. A big volume is essential to serve as a buffer storage: for a fully equipped 90 m² melter, an overall tonnage of 275 tpd might have leaps of about 50 tpd so that the working end must be designed as a kind of distributor channel to supply well-conditioned glass to 3–4 IS machines. For float or fiber glass, in contrast, melter design does not differ so much in Europe and America.

5.2 Empirical Guidelines

Most helpful to the furnace designer are general empirical rules that are part of the company's know-how as well as design criteria also based on experience. Not following them makes it difficult to manufacture a marketable product or to keep energy consumption, hence production costs, within reasonable limits. Although they depend on glass types, many are valid for all furnace types using fossil fuel as the main energy source. In furnace engineering parlance, an important parameter is the *load* (Chapter 9.8), which has already been mentioned and is the production rate per unit of surface area expressed in tons per day and square meter (t/d.m²). In furnace design and construction, a modified quantity, the so-called *fossil load* plays a key role. It is defined as the fraction of the *load* sustained by the input of fossil fuel energy alone. Reaching a sufficiently high fossil load is the initial objective of furnace design; it is determined by the melting area, the length to width ratio, the height of the crown, the burner configuration, and many other construction details. The load ultimately envisaged is chiefly achieved by boosting (typically 5–30% depending on the type of glass). For this purpose, the configuration of electrodes and the dimensions of the melting space have to be designed accordingly as will be illustrated in the next section.

The more difficult it is to melt a specific glass, the more additional installations and tools need to be integrated if a high glass quality is desired. Of utmost importance in this respect is a long enough residence time in the *melting end*, including the refining part of bank, and not in the whole melter as commonly assumed. Depending on cullet fraction, glass quality, and tonnage leaps, between 18 and 20 hours are assumed to be optimal for container glass, out of average total 24 hours spent in the melter. For tableware, these figures are 26–28 and 30 hours, and they should be higher than 48 hours for special glasses.

The higher the wall, however, the more attention must be paid to avoid a stagnant area, for example, with bubbling or by boosting, which in addition stabilizes the convection current, especially in big furnaces. Boosting is in addition a good tool for modifying the temperature of the

throat inlet, the riser, and further the entrance temperature of the distributor. The higher the planned job changes in terms of tonnage differences and the more frequently these are to be put into effect, the higher an installed dam wall has to be and the deeper the refining part has to be depending on glass type.

Regarding melter geometry, the higher the specific total load of the melting end (fossil and electric proportion), the deeper the melting end must be. The narrower and smaller ($<50 \text{ m}^2$) the melting surface, the lower the glass bath must be and the lower the specific melting output can be.

The darker the glass color, the lower the fossil melting load (flint/amber/green, some green colors can only be melted with a proportion of electric boosting or if a bubbling system is installed).

In all cases, the customer's practice is of vital importance. If side electrodes are integrated in the soldier blocks of the melting end, boosting can be used when needed with a certain basic load. But dirty bottom glass is stirred up if boosting is switched on again after a certain downtime, which first leads an increased number of seeds and inclusions. With a bottom boosting system, the bath depth must not be too low otherwise no efficient convection current can be sustained. On the other hand, maintaining the required temperatures in a deeper bath can require continuous boosting. But bottom boosting is not always compatible with a high cullet fraction because introduction of metal impurities may result in leakage and total loss of the furnace.

Although float-glass furnaces have enormous dimensions, their capacity can be compared with those of container glass. The melting part can be exposed to a specific load up to 2.5 t/d.m^2 depending on size, color, and cullet fraction. Bubblers are used for tinted glass, which are inserted to a depth of about 600 mm into the glass bath. An advantage of bubbling systems available on the market, as proposed by F.I.C. UK, is that they can be activated as a function of the color of the glass melted. Another current trend is to use more and more boosting systems with up to 2.5 MW capacity in single circuits and up to about 6 MW maximum capacity to make optimum use of the operating systems. The refining part of such a float glass furnace must also be obviously able to handle this additional capacity, the same applying to the waist and working end. Specific loads up to about 4.5 t/d.m^2 in the refining part and up to about 5 t/d.m^2 in the working end are now not uncommon.

5.3 Increasing the Specific Load: An Example with Amber Glass

The influence of the operating parameters on production costs for different overall loads per square meter of

Figure 7 Energy consumption as a function of specific load (t/d.m^2) used to optimize economic furnace design for tableware and container glasses.

melting surface will be illustrated for tableware and container glass for which the energy optimum is for fossil loads ranging from 2.3 to 2.7 t/d.m^2 (Figure 7). When producing amber glass with 35% cullet, a small 45 m^2 end-fired furnace can be loaded with about 2.35 t/d.m^2 and heated with fossil fuel only to produce 105 tpd of good-quality glass having between 30 and 60 seeds/100 g, which complies with the European standard. Because it is fossil fired, the furnace cannot be very deep as bottom temperatures would be too low and glass quality insufficient. With a dam and bubblers, production could increase to 110 tpd with the same cullet fraction and glass quality, and to 135 tpd with additional boosting. For a similar furnace twice as great, i.e. of 90 m^2 size, the specific load can be 2.45 t/d.m^2 from the start, thus producing 235 tpd. This figure could be brought to 265 tpd with side boosting and to even 275 tpd in combination with bottom boosting, in which case the bath depth has to be increased.

Up to 475 t/d of the same amber glass can be melted in a 180 m^2 end-fired furnace whose length of about 18 m imposes from the start an additional tool to stabilize the convection current. Although about 500 tpd can be attained with bubbling, a designer will prefer bottom boosting. Depending on the number and diameters of the electrodes, up to 2600 kWh can be supplied directly into the glass to increase capacity to 570 tpd. The overall installed boosting capacity obviously needs to be higher. With additional boosting in the melting end, preferably at the bottom for a large size, the overall tonnage can be increased from 700 to about 720 tpd provided that the bath depth has been increased accordingly.

With a 90 m^2 oxyfuel furnace, one could certainly melt up to 250 tpd of amber glass depending on oxygen purity. With regard to energy, the efficiency would at first sight certainly be the best but the energy required to produce

oxygen would of course have to be included. Also note that the figures reported for amber glass would not apply to flint glasses, for which the specific load could be higher, and for green glass, which does not melt so well and for which the iron and chromium contents have to be taken into account. Regardless of glass color, the load broadly increases in the order lead crystal, crystal, cover, and aluminosilicate glass, followed by fiber, borosilicate, and float glass, the highest loads being achieved with container glass. In general, loads can be increased by boosting, often in combination with bubbling. In summary, these amber data are only rough guidelines, which can also vary much for a given type of glass with the raw materials used and their purity. Hence, many factors must be considered to estimate which particular configuration should be most profitable for a given type of production.

6 NO_x Emissions

An NO_x value of 800 mg/Nm³ for an 8% O₂ content and a dry waste gas represents 1.2 kg of NO_x per ton for container and float glasses. This figure was regarded as a magic limit way out of reach in the 1990s. At the price of an increased energy consumption, it is nowadays the limit in front of the chimney set in Germany whereas environmental authorities aim at 500 mg/Nm³ for new regenerative end-fired or cross-fired furnaces [5]. For oxyfuel furnaces, the limiting value is not referred to the Nm³ flue gas, but to the amount of glass melted.

These pollutants form from nitrogen in the fuel and the raw materials, especially when nitrates are present in the batch. The formation of NO_x from atmospheric oxygen and nitrogen can take place by different routes [13]. The first identified were the so-called Zel'dovich mechanisms [14], namely a slower reaction

followed by the much faster

But NO can also form through reactions with OH radicals or via *prompt* mechanisms [15] taking place in the flame front near the burner surface via attacks of carbon or hydrocarbon radicals on N₂ molecules such as

The NO_x emission levels thus greatly depend on the fuel used, (excess) oxygen content, and CO content in the flue gas. Because the furnace itself also matters, other factors to be considered are its length to width ratio, superstructure height, regenerator size, and number and type of burners as emissions are lowered with fewer burners, reduced superstructure temperatures, and lower preheating temperatures of the combustion air. If more than three burners per port are used for end-fired furnaces, an increase of the NO_x values from 100 to 300 mg/Nm³ NO_x per additional burner is to be expected, depending on the burner type and design. Similar correlations can be seen in cross-fired furnaces.

An efficient method to lower NO_x emission is to increase the CO content in the regenerator head (Table 4), but values higher than 1500 ppm may cause checker breakdown via disintegration of the refractories as a result of microcracking or even powdering. The cause is the formation of iron carbides between 400 and 600 °C from the carbon produced by the Boudouard reaction

This reaction takes place by chemisorption of CO and its subsequent decomposition catalyzed by active Fe atoms produced by the reduction of iron oxides present in the refractories, which then participate in a second reaction to produce iron carbides [16].

Alternatively, mixing the combustion air with part of the exhaust waste gas in the downpart of the regenerator can help to lower NO_x emissions right from the reaction

Table 4 Correlation between CO and NO_x contents.

Position	CO content (ppm)		
Regenerator head	<50	<300	600–800
Regenerator downpart	None	<50	100–300
Chimney front	None	None	<100
	Corresponding NO _x content (mg/Nm ³)		
Two burners installed	550–750	500–600	450–500
Three burners installed	700–900	600–800	<700

Figure 8 Interplay of factors involved in NO_x and SO_x emissions.

with the fuel at the port mouth. But the complex balance of factors to be considered also involves SO_x species (Figure 8). A lower air preheating temperature, for example, results in lower NO_x levels, but then both the energy consumption and the SO_x content in the flue gas increase and the achievable pull rate decreases, and vice-versa.

Experienced practitioners know so well these correlations that primary reduction of NO_x has almost reached its limits; potential improvements might concern only burners whose emissions could be brought down to about 300 mg/Nm^3 per unit. Further, NO_x decreases should thus rely on shifts of the gas-phase equilibria by selective non-catalytic reduction reactions [17]. A relevant reaction is [18]

which is beneficial from 1000 down to 700 and 870°C depending on whether or not H_2 is added to the system. Temperatures higher than 1000°C should be avoided, however, because the adverse reaction

then predominates. Considerable reductions of the NO_x values in front of the chimney can thus be achieved through injection of ammonia or ammonia solutions into the flue gas within the right temperature window, but the investment and operating costs can amount to about 100 k€ per year depending on plant size and flue gas volume flow to be treated.

7 Perspectives

From the mid-twentieth century, a general trend in glass-making has been to develop bigger units as exemplified not only for float but also for container glass for which the IS machines keep increasing in size and production volume (Chapter 1.5). Owing to increasing industrial concentration, this trend will likely continue in the future so that small furnaces will probably remain only for

producing special or highest-quality glasses. Multicolor furnaces for container glass are, for instance, designed to be highly flexible – and therefore smaller – with only one or at most two IS machines to speed up reactions in response to market situations. For usual container glass, the size of cross-fired furnaces will in contrast approach 230 m^2 to ensure an output of 1000 tpd. For float glass, 1000 tpd will no longer be a limit, thanks to future improvements brought to the tin bath and annealing lehr, and especially to faster operations at the cold end where the ribbon is cut and withdrawn. For lower outputs in the 600–700 tpd range, end-fired furnaces will be increasingly built in view of their enormous savings in investment costs. Once they have been implemented and the right conclusions drawn, these furnaces will certainly become larger.

Progress will also be made for the refractories. To summarize the considerable improvements already brought to their properties, it will suffice to state that in the 1930s their campaign lives and maximum temperatures were only 11–13 months and 1400°C [1]. By comparison, the service life of furnaces currently reaches about 15 and 20 years for container and float glass, respectively, during which there can be short periods of hot repair of local defects in the upper structure or, more rarely, complete shutdown and release of melt for cold repair of critically corroded areas in the lower structure. For fossil-fuel furnaces, more ceramic-bonded AZS materials will certainly be used and additional advantages will accrue if the basic idea of compound materials such as the sandwich or zebra blocks is picked up. For the superstructure, 190–250 mm blocks of pure AZS could, for example, be replaced by 75–100 mm AZS sandwich blocks, which would ensure, in combination with high-alumina refractories, the same stability and application limits. Considerable savings in investment costs could be made in this way, which would in addition limit tapping expensive zirconium resources.

In the past decade, alternative melting technologies have been thoroughly developed with the aim to increase both energy utilization and production efficiency. These

Figure 9 Evolutions of overall energy efficiency and emissions of NO_x , SO_x , and dust over the years. Source: Data from <http://www.agc-glass.eu/en/sustainability/environmental-achievements/air>

approaches comprise: (i) submerged combustion technology whereby burners deliver in a bubbler-like manner their flames from the bottom of the melting space directly into the melt; (ii) inflight technology whereby a finely ground batch is delivered directly into the flames; (iii) top vertical burners whose flames impinge on the melt surface. Even though the last one is now applied by several producers, for example, for fiber glass, none of them have fared significantly better than conventional technologies with respect to the intended goals.

From an environmental standpoint, one should finally stress the impressive nature of the improvements brought over the years (Figure 9 and insets). The evolution of the energy efficiency is especially striking with more than ten times increase since 1880, whose leveling off might suggest that the intrinsic limits of current processes are being approached. This reduction of the melting energy from 5600 kWh/t in the 1930s to 1000 kWh/t today for container glass has been largely attributable to the improvements in refractory materials. Of more recent concern are the NO_x and SO_x emissions, which a company such as AGC has been able to decrease by a factor of 4 in 20 years. A similar trend is observed for the emissions of dust, which is mainly made up of sulfates. These reductions are achieved with filters. Whenever possible the dust collected is recycled as sulfate batch components.

But enormous investments remain to be made by the glass industry at large to comply with the legal requirements worked out by the EU for NO_x emissions because many plants do not benefit yet from up-to-date technologies. New development are also being made, for example, for big all-electric melters for which, however, another challenge will be really permanent energy sources. And it will be seen whether new procedures such

as thin-melting processes or submerged-burner systems will be more successful on the market than others that have been developed in the past. As for the move toward a CO_2 -free production, it would involve a still more difficult challenge as carbonates should be eliminated from the batch, which would require major changes in the raw materials used ever since the beginnings of glassmaking.

Physics and Modeling of Glass Furnaces

Reinhard Conradt¹ and Erik Muijsenberg²

¹ RWTH Aachen University, Aachen, Germany

² Glass Service a.s., Vsetin, Czech Republic

1 Introduction

Glass furnaces, their construction and operation, play a key role in industrial glass manufacturing for the obvious reason that the melting stage is the starting point of all further operations. The primary objectives of melting are (i) glass quality, (ii) production efficiency through a high production rate relative to the furnace size, and (iii) environmental sustainability, i.e. minimization of both energy demand per unit mass of produced glass and release into the environment of CO₂, dust, SO_x, NO_x, HCl, HF, etc. These objectives are actually somewhat conflicting [1] as travel comfort, speed, and fuel consumption are in a car journey. Because the challenge consists in finding optimum compromises between the primary objectives, any furnace necessarily depends on the production intended and on its volume and can in addition display specific construction features (Chapter 9.7).

Glass can be heated with either fossil fuel or electricity and melted either in tank furnaces operated continuously or in pot or crucible furnaces working discontinuously. All-electrical as well as discontinuously operated pot and crucible furnaces are relevant to the production of crystal glass tableware, specialty, and art glass. For insulation fibers (Chapter 9.3), some manufacturers use metallurgical-like *cupola* furnaces whereby a packed bed of coal is in direct contact with the raw materials and the melt. In the flat- and container-glass industries, however, continuously operated fuel-fired furnaces with an additional electrical boosting are largely prevailing. These furnaces will thus be the focus of the present chapter.

Hence, the fundamental physical principles governing the work of glass furnaces as heat exchangers and chemical reactors will first be presented in terms of the key parameters characterizing these functions. Next, the relevant heat balances will be set up with special attention to the determination of the heat transferred to the melt, which will be made through the theory of heat exchangers supplemented by a simple model of radiative heat exchange. From an economic standpoint, two fundamental questions will then be discussed, namely the dependence of furnace operation on the production rate and the input–output characteristics of the furnace as a chemical reactor. As a complement to the theoretical methods presented in Chapter 1.7, some practical aspects of furnace modeling will finally be discussed with emphasis on locally and temporally resolved pictures of the intrinsic heat and mass transfer processes involved.

Notations

The following dimensionless quantities are used:

ζ	temperature efficiency
NTU	number of (heat) transfer units
z_{HL}	heat capacity-flow ration between hot and cold stream

Energies and derived quantities (powers, heat fluxes) are specified by the following indices:

ex	exploited heat; it comprises the latent heat content of the melt at exit temperature and the reaction heat of the (mostly endothermal) thermochemical reactions of the batch-to-melt conversion
fire	heat exchanged with the furnace body, i.e. the batch, the melt, and the refractories
flue	heat carried by the flue gas leaving the combustion space and entering the heat-recovery system

H	referred to the hot stream or the combustion space
ht	heat transferred across the hearth surface
in	energy input by fuel and electric boosting
L	referred to the cold stream or the melting compartment
re	heat recovered by the heat-recovery system
sf	total heat set free in the combustion space
stack	heat carried by the flue gas leaving the heat-recovery system
X	referred to the heat recovery system
w	wall losses, distinguished as w_H , w_L and w_X

2 Furnace Parameters

2.1 Basic Configuration of a Tank (or Hearth) Furnace

The majority of furnaces consist of a shallow basin whose dimensions $V_L = \text{length } L \times \text{width } W \times \text{depth } D$ are typically $V_L = 10 \times 6 \times 1 \text{ m}^3$ for container and $30 \times 10 \times 1.4 \text{ m}^3$ for float glass. This *melting space* is in direct contact with the *combustion space* of volume V_H whose cover is arched (the crown) and side walls are vertical. The subscripts H and L designating here *high* and *low* refer to the combustion and melting spaces, respectively, and will also be used to denote the corresponding mass flows, i.e. the hot and cold streams. Heat transfer from V_H to V_L takes place across the hearth area $A = L \times W$ such that a typical 5–20% share of energy is delivered to V_L by electrical boosting via submerged electrodes.

As a heat exchanger, the furnace operates along three principal temperature levels: first, the environmental temperature T_0 of about 25°C ; second, the constant exit or pull temperature T_{ex} of typically $1320 \pm 20^\circ\text{C}$ at which the molten glass leaves the melting space; third, the so-called adiabatic flame temperature T_{ad} , which denotes the highest temperature that could be reached if the entire heat set free in the combustion process were stored in a thermally isolated flue gas. Although this temperature is not reached anywhere in the combustion space, its thermodynamic importance stems from the fact that it plays a key role in the thermal efficiency of a furnace. The adiabatic temperature depends on the amount of energy carried by the fuel and recovered from the hot flue gas. It can thus be readily calculated from the heat capacity of the flue gas, whose variations with temperature may be accounted for by equations of the type $c_{\text{flue}} = A + B T + C T^2 + \dots$. Typical T_{ad} values are 2440, 2500, and $2880 (\pm 25)^\circ\text{C}$ for air-gas, air-oil, and oxy-gas firing, respectively. In contrast to T_{ad} , T_{ex} , and T_0 , the flue-gas exit temperature T_{flue} does not constitute a boundary condition of the furnace operation; it is rather determined by the actual heat-exchange process.

2.2 Units and Reference States

Masses will be given in metric tons, times in hours, mass flows in t/h, temperatures in $^\circ\text{C}$, and densities (ρ) in t/m^3 . For a glass melt, the density may be taken as 2.4 t/m^3 whereas its values are 1.288, 0.716, 1.965, and $0.804 \cdot 10^{-3} \text{ t/m}^3$ for air, natural gas, CO_2 , and H_2O , respectively. Gas volumes are conventionally referred to *normal conditions* defined as 0°C and 1 atm, which thus differ from the 25°C and 1 bar generally used for thermodynamic standard states. Although the 1 m^3 volume of an ideal gas under the former conditions translates into 1.106 m^3 under the latter, energies depend little on which reference state is chosen.

For example, the enthalpy of the reaction

termed the net calorific value H_{NCV} , amounts to 802.6 and 802.4 kJ/mol for the normal and thermodynamic reference states, respectively. Because the difference is negligible, energies may be calculated relative to the thermodynamic standard state as usual. They will be consistently given in kWh for immediate conversions into electrical energy equivalents. Conversion factors with other units are $1 \text{ kWh} = 3.6 \text{ GJ} = 860.4 \text{ kcal} = 3412 \text{ BTU}$.

Heat capacities are given in $\text{kWh}/(\text{t}\cdot\text{K})$ unless stated otherwise. In heat transfer, what actually matters is the product of the mass flow (m') and heat capacity $m'_H \cdot c_H$ and $m'_L \cdot c_L$ of the hot and cold streams, respectively, which are thus expressed in kW/K .

3 The Physics of Glass Furnaces

3.1 Key Indicators

Referring to Chapter 1.1 for a general description of the chemical processes that take place in furnaces, we will first consider only their thermal aspects. The overall thermal performance of a system (Figure 1) is characterized by three dimensionless quantities as key indicators. The first is the *temperature efficiency* ζ , defined as a dimensionless parameter in terms of the three aforementioned temperatures:

$$\zeta = \frac{T_{\text{ex}} - T_0}{T_{\text{ad}} - T_0}. \quad (2)$$

This indicator has the advantage of summarizing the ultimate result of the heat exchange process, i.e. the ratio of the temperatures of cold stream at exit and hot stream at entry, both relative to the environmental temperature. It is a special feature of glass furnaces – in contrast to heat exchangers in general – that the value of ζ is fixed: For a given fuel and combustion mode (air-gas or oxy-fuel),

Figure 1 Fundamental parameters controlling a furnace in its dual functions as a heat exchanger and a chemical reactor over a hearth area A with a heat transfer coefficient α_{ht} ; adiabatic, exit, and flame temperatures, and heat capacity mass flows and dwell times of the hot and cold streams.

hence, for a given T_{ad} , the temperature efficiency ζ is fixed by the technological requirement to keep the glass exit temperature T_{ex} constant within narrow bounds. For air-gas and oxy-fuel combustion, ζ assumes a value of about 0.53 and 0.46, respectively.

The second key indicator is the dimensionless heat capacity-flow ratio given by

$$z_{HL} = \frac{m'_H \cdot c_H}{m'_L \cdot c_L}. \quad (3)$$

In general terms, this indicator compares the power delivered by the hot stream to the power uptake by the cold stream at an infinitely large exchange interface or at infinitely fast heat transfer rate. An inspection of z_{HL} has direct practical consequences: if a furnace suffers from a heat capacity-flow mismatch, reflected by a z_{HL} very different from unity, then furnace performance cannot be improved by measures enhancing the heat-transfer rate (like reduction of a foam layer, use of strongly radiating flames, etc.).

The third key indicator is the dimensionless number of transfer units, NTU, which is a measure of the finite heat transfer rate across the hearth surface:

$$NTU = \frac{\alpha_{ht} \cdot A}{m'_H \cdot c_H}, \quad (4)$$

where A is the hearth surface area and α_{ht} the mean heat transfer coefficient between the combustion and melting spaces, expressed in $\text{kW}/(\text{m}^2 \text{ K})$.

These three indicators are linked by the relation $\zeta = f(z_{HL}, NTU)$. Algebraic formulae are available for simple geometrical standard configurations only (see Eq. 14a, b). Since ζ is kept constant in furnace operation, z_{HL} and NTU cannot be optimized independently; they rather depend on each other.

The overall mass flow performance of a system (Figure 1) is described in relation to the nominal (or geometrical) dwell time $\tau_{L,nom}$ of the cold stream in the melting space. It is simply defined as $\tau_{L,nom} = \rho_{melt} \cdot V_L / p$, where $p = m'_L$ is the glass production rate. It is of the order of 20–40 hours. The dwell time $\tau_{L,nom}$ allows one to describe the response of a furnace as a chemical reactor in terms of a dimensionless timescale $z = t/\tau_{L,nom}$, hence, to compare furnaces of different sizes and production yields. The nominal dwell time of the hot stream $\tau_{H,nom}$ is smaller than $\tau_{L,nom}$ by approx. four orders of magnitude. It suffices here to state that it is about 5 seconds.

3.2 From Heat Balance to Furnace Efficiency

Modern furnaces include flue-gas heat-recovery systems (Figure 2). Their heat balance may be described in three different ways: (i) as a power balance, P in kW; (ii) as a balance of energies per ton of produced glass, H in kWh/t; (iii) or as heat fluxes, q , in kW/m^2 per unit hearth area A . These quantities are mutually related by $P = H p$, $q = H r$, $r = p/A$, where p and r thus denote the production rate expressed in t/h and in $\text{t}/(\text{m}^2 \cdot \text{h})$, respectively. Illustrating that the compromises made between quality and throughput depend on the type of glass produced, furnaces typically have r values of 0.13–0.16 $\text{t}/(\text{m}^2 \cdot \text{h})$ for containers but only 0.07–0.10 $\text{t}/(\text{m}^2 \cdot \text{h})$ for float, corresponding to 3.2–3.8 and 1.7 to 2.4 $\text{t}/(\text{m}^2 \cdot \text{d})$, respectively.

Operationally, an important parameter is of course the power input $P_{in} = H_{NCV} \cdot V'_F$, where H_{NCV} is the net calorific value of the fuel and V'_F the volume flow of fuel under normal conditions. The net calorific value depends on whether or not the water of the flue gas remains

Figure 2 Heat balance of a fuel-fired furnace equipped with a flue-gas heat-recovery system; the exploited heat comprises both the latent heat content of the melt at pull temperature and the heat demand of chemical reactions of the batch-to-melt conversion.

gaseous. If not, the condensation heat must be taken into account into the gross calorific value H_{GCV} , which is thus about 10% higher than H_{NCV} (e.g. 11 vs. 10 kWh/m³) for natural gas. The difference has definite economic implications because the prices quoted by fuel suppliers refer to H_{GCV} whereas the amount of energy useful for the process is H_{NCV} .

With electric boosting, then $P_{in,total} = P_{in,F} + P_{boost}$ where the subscript F denotes fuel. For simplicity, this boosting will not be taken into account in the following although it would be readily accounted for. The useful power drawn from the furnace, P_{ex} , is also termed the exploited power. To account for chemical reactions within the batch and the heat content of the melt, one expresses it as $P_{ex} = H_{ex}p$. The parameter p is the production rate and H_{ex} is given by

$$H_{ex} = (1 - y_C) \cdot \Delta H_{chem}^\circ + \Delta H(T_{ex}), \quad (5)$$

where y_C is the amount of cullet per ton of produced glass, ΔH_{chem}° the standard chemical heat demand of the batch-to-melt conversion (referred to 25 °C, 1 bar), and $\Delta H(T_{ex})$ the heat content of the melt at the exit temperature T_{ex} .

The principal balance (Figure 2) then reads

$$P_{in} = P_{ex} + P_{loss}, \quad (6)$$

where the cumulative loss P_{loss} comprises all wall losses and the power carried by the flue gas when leaving the cold end of the heat-recovery system.

Both P_{in} and P_{ex} , and hence, by difference, P_{loss} , are thermodynamic functions of state. Because they do not depend on the actual paths of the combustion and melting processes, they can always be calculated accurately. The same applies to the overall efficiency of heat exploitation η_{ex}

$$\eta_{ex} = P_{ex}/P_{in}. \quad (7)$$

Two further balance equations are derived. The power P_{sf} set free in the combustion space amounts to

$$P_{sf} = P_{in} + P_{re} = P_{flue} + P_{fire}, \quad (8)$$

where the subscripts re, flue, and fire mean recovered from the flue gas, lost with it, and exchanged with the furnace body, respectively (Figure 2). For a given production rate p , P_{sf} is the power required to sustain the glass quality desired. If, for example, a problem occurs with the heat recovery system such that P_{re} goes down, then P_{in} has to be adjusted accordingly to sustain a constant P_{sf} .

Since P_{flue} is the power leaving the combustion space, it is the portion of P_{sf} that is not exchanged with the furnace body. The power actually exchanged with this body thus is

$$P_{fire} = P_{wH} + P_{ht} = P_{wH} + P_{wL} + P_{ex}, \quad (9)$$

where P_{ht} is the power transferred to the melting space and P_{wH} and P_{wL} that lost to the walls.

Both Eqs. (8) and (9) are useful to pinpoint areas of strong and weak performances of a furnace, for example, in terms of the

combustion space efficiency	$\eta_{sf} = P_{fire}/P_{sf}$
heat transfer efficiency	$\eta_{ht} = P_{ht}/P_{in}$
efficiency of heat recovery	$\eta_{re} = P_{re}/P_{flue}$
furnace insulation efficiency	$\eta_w = 1 - (P_{wH} + P_{wL})/P_{in}$

3.3 Toward Energy Savings

As instructive as these quantities may be, their practical usefulness is limited by the uncertainties that beset their individual terms and thus make their evaluation more difficult than that of the power input P_{in} in Eq. (6). Owing to the complex structure of a real furnace (Chapter 9.7), calculations of heat transfer across the refractory walls yield rough estimates at best. Because P_{flue} and P_{re} are related to the volume flows of flue gas and combustion air, respectively, the cumulative wall losses $P_{wH} + P_{wL}$ can be better assessed from the difference between Eqs. (8) and (9). The temperatures T_{flue} (exit temperature of flue gas) and T_{re} (entry temperature of preheated air) need also to be known although their measurements are fraught with technical difficulties. In a first step, the volume flows V'_{flue} and V'_{air} must also be determined. For a hypothetically stoichiometric combustion, they are directly related to the flow of fuel V'_F and to the volume ratios n_{flue} and n_{air} of flue gas to fuel and air to fuel, respectively. In real combustion processes, an air excess λ of $\lambda = 1.02$ – 1.08 has to be used. When the simple combustion reaction is written

the coefficient $7.52 = 2(79/21)$ thus reflects the approximate composition of air with 79% N₂ and 21% O₂. It follows that $n_{flue} = 10.52$, $n_{air} = 9.52$, and $n_{air}/n_{flue} = 0.9$.

All these parameters are mutually related by the following equations, which also take into account the flow V'_{bg} of gases released from the batch:

$$V'_{flue} = (n_{flue} + (\lambda - 1) \cdot n_{air}) \cdot V'_F + V'_{bg}, \quad (11a)$$

$$V'_{bg} = (m'_{batch} - p) \cdot (V^{id}/M_{bg}), \quad (11b)$$

$$V'_{air} = \lambda \cdot n_{air} \cdot V'_F, \quad (11c)$$

$$P_{flue} = V'_{flue} \cdot c_{flue} \cdot (T_{flue} - T_0), \quad (11d)$$

$$P_{re} = V'_{air} \cdot c_{air} \cdot (T_{air} - T_0). \quad (11e)$$

Here, m'_{batch} is the mass flow of batch in t/h, $V_{\text{id}} = 22.4 \text{ m}^3/\text{kmol}$ is the volume of ideal gases, and M_{bg} the average molar mass of batch gases in t/kmol. From Eqs. (11d) and (11e), one determines the efficiency of the heat recovery system as

$$\eta_{\text{re}} = \frac{P_{\text{re}}}{P_{\text{flue}}} < \frac{n_{\text{air}}}{n_{\text{flue}}} \cdot \frac{c_{\text{air}}}{c_{\text{flue}}}. \quad (12)$$

The efficiency is always smaller than the product of the ratios $n_{\text{air}}/n_{\text{flue}}$ and $c_{\text{air}}/c_{\text{flue}} \approx 0.9$, which thus sets an upper bound of 0.81. If the wall losses P_{wX} are taken into account, lower values in the range 0.55–0.65 are actually obtained upon finite-time operation. Combining Eq. (8) and (11a–e) and solving for V'_{F} , one finally expresses the fuel demand as

$$V'_{\text{F}} = \frac{(1 - \eta_{\text{re}}) \cdot c_{\text{flue}} \cdot V'_{\text{bg}} + P_{\text{wH}} + P_{\text{wL}} + H_{\text{ex}} \cdot p}{H_{\text{NCV}} - (1 - \eta_{\text{re}}) \cdot (n_{\text{flue}} \cdot c_{\text{flue}} + (\lambda - 1) \cdot n_{\text{air}} \cdot c_{\text{air}}) \cdot (T_{\text{flue}} - T_0)}. \quad (13)$$

Through its different terms, this equation summarizes the various ways of saving energy by conventional means. Clearly, V'_{F} is minimized, if

- η_{re} is maximum;
- V'_{bg} is low, i.e. if one uses only raw materials releasing small gas volumes;
- furnace walls are well insulated, although the corrosion of their refractory materials is another factor to be considered;
- H_{ex} is minimized, for instance, with high amounts of cullet or raw materials having a low chemical heat demand in the batch-to-melt conversion;

- T_{flue} is kept low by adequate design for both burner and combustion technology;
- the air excess λ is also kept low, and an influx of *false air* (i.e. air sucked into the furnace by the action of the off-gas system) is avoided.

3.4 Intrinsic Heat Transfer

In the heat balance (Figure 2; Eq. (9)), a crucial term is the power transferred from the combustion to the melting space, P_{ht} . Because the conventional heat balance does not yield it directly, two different approaches can be followed. The first makes use of the standard equations for heat exchangers in terms of two of the aforementioned key indicators, namely z_{HL} and NTU:

$$\frac{P_{\text{ht,counter}}}{P_{\text{in}}} = \frac{1}{z_{\text{HL}}} \cdot \left[1 - \frac{1 - z_{\text{HL}}}{1 - z_{\text{HL}} \cdot \exp(-\text{NTU} \cdot (1 - z_{\text{HL}}))} \right], \quad (14a)$$

$$\frac{P_{\text{ht,co}}}{P_{\text{in}}} = \frac{1}{1 + z_{\text{HL}}} \cdot [1 - \exp(-\text{NTU} \cdot (1 - z_{\text{HL}}))]. \quad (14b)$$

Here, the subscripts *counter* and *co* denote the counter-directed hot stream and the codirected flow of the cold stream, respectively (Figure 1). Although the actual situation is more complicated, the overall performance is well represented by the arithmetic mean of these base cases (Figure 3a). The ratio $P_{\text{ht}}/P_{\text{in}}$ is a sensitive function of both the heat capacity ratio z_{HL} and the conditions of heat transfer as reflected by the NTU. From daily factory records collected over a period of two years, a survey of 23 different container-glass furnaces has revealed that

Figure 3 Efficiency of a glass furnace as a function of the heat capacity-flow ratio z_{HL} . (a) Power transferred to the melting space from the power input, $\eta_{\text{ht}} = P_{\text{ht}}/P_{\text{in}}$, for the indicated values of the number of transfer units (NTU); (b) overall efficiency $\eta_{\text{ex}} = P_{\text{ex}}/P_{\text{in}}$ of 23 container-glass furnaces at their optimum working point; circles: air-fuel end-port furnaces; crosses: air-fuel cross-fired furnaces; triangles: oxy-fuel furnaces.

NTU varies within a narrow margin from 0.5 to 1.2. Any technical attempt to enhance NTU can work only if the heat capacity flows are well balanced, i.e. if z_{HL} assumes a value close to 1 (Figure 3a). This is why the overall efficiency of heat exploitation calculated with Eq. (7) strongly decreased with increasing z_{HL} in this survey (Figure 3b).

Many furnaces suffer from unbalanced flow because z_{HL} is not well constrained. This applies especially to cross-fired air-fuel container-glass furnaces. On the other hand, the obvious advantage of oxy-fuel furnaces primarily rests much more on their excellent flow balance than on their elevated T_{ad} . Economically, however, this advantage has to be put into relation with the oxygen cost. It is true that one can improve the flow balance by operating a furnace at a small air excess, by avoiding false air, and by an adequate boosting. But z_{HL} is a basic parameter in furnace construction and combustion technology that is determined by the volume of the effective combustion space relative to the hearth area and by the effective cross section available for the flow.

For evaluating P_{ht} , an alternative approach rests on a simple radiation model (Figure 4). In general terms, the incident radiation (I) is transmitted (Tr), absorbed (Ab), or reflected (Rf): $I = Tr + Ab + Rf$. For heat radiation in a furnace, $Tr = 0$. According to Kirchhoff's law, the absorbed part is equal to the heat E emitted as thermal radiation so that $I = E + Rf$. As given by Stefan-Boltzmann's law, $E = \epsilon \sigma \cdot T^4$, where $0 < \epsilon < 1$ is the emissivity of the radiating volume or surface and $\sigma = 56.7 \cdot 10^{-12} \text{ kW}/(\text{m}^2 \cdot \text{K}^4)$ a universal constant. A black body ($\epsilon = 1$) at $T = 1000 \text{ K}$ thus emits $56.7 \text{ kW}/\text{m}^2$. The balance of heat radiation in a furnace can be described in terms of heat fluxes q normalized to the hearth area,

$q = P/A$ in kW/m^2 (Figure 4). The glass melt is approximated as a surface radiator, which is a good approximation for amber and Cr-green glass but a fair estimate at best for flint (white) glass. The heat-flux balance constitutes the following system for the four fluxes exchanged between the melt, gas, and crown (Figure 4):

$$q_1 = \sigma \cdot \epsilon_{\text{melt}} \cdot T_{\text{melt}}^4 + (1 - \epsilon_{\text{melt}}) \cdot q_2, \quad (15a)$$

$$q_2 = \sigma \cdot \epsilon_{\text{gas}} \cdot T_{\text{gas}}^4 + (1 - \epsilon_{\text{gas}}) \cdot q_3, \quad (15b)$$

$$q_3 = \sigma \cdot \epsilon_{\text{crown}} \cdot T_{\text{crown}}^4 + (1 - \epsilon_{\text{crown}}) \cdot q_4, \quad (15c)$$

$$q_4 = \sigma \cdot \epsilon_{\text{gas}} \cdot T_{\text{gas}}^4 + (1 - \epsilon_{\text{gas}}) \cdot q_1. \quad (15d)$$

The emissivities ϵ of the melt, gas, and crown are labeled accordingly. The heat flux $q_{ht} = q_2 - q_1$ is derived directly from the solution of this system (see Appendix). As an example, one can select $T_{\text{melt}} \approx 1500^\circ\text{C}$, $T_{\text{gas}} \approx T_{\text{crown}} \approx 1600^\circ\text{C}$; $\epsilon_{\text{crown}} \approx 0.5$, $\epsilon_{\text{melt}} \approx 0.6$, $\epsilon_{\text{gas}} \approx 0.13$ and 0.4 for air-gas and oxy-gas combustion, respectively [2]. Then the resulting fluxes q_{ht} are 60 and $73 \text{ kW}/\text{m}^2$, respectively.

3.5 Process Irreversibility and Rate Dependence

As useful as a heat balance may be, it is an incomplete representation of furnace performance. Its first shortcoming is it rests on the first Law of thermodynamics only so that a given amount of heat Q does not tell anything about its usefulness in a process. If 1200 kWh are, for instance, needed to melt one ton of glass, this heat must be available at the temperature T_{proc} of the process. If it were available at 500°C only, then bringing it to T_{proc} would reduce its amount by at least a factor $Q(1 - T_0/T_{\text{proc}})$. Because the entropy $S = Q_{\text{rev}}/T$ is a measure of energy degradation, only the fraction $P_{\text{in}}(1 - T_0/T_{\text{proc}})$ of the input power is then actually available. By contrast, electrical power $P_{\text{in,boost}}$ is available to almost 100%, thanks to extremely high Fermi or electron temperatures T_e in electrode materials, whose range $5 \cdot 10^4 - 10^5 \text{ K}$ implies that the term T_0/T_e is close to zero. As a second shortcoming, a heat balance presents a snapshot of furnace performance for only a given production rate. Time is not involved as an explicit parameter although it badly needs to be considered with respect to entropy production in any process involving transport phenomena and finite conductivities [3].

In other words, energy degradation and finite time constraint constitute a fundamental bottleneck for furnace operations. Obviously, large temperature differences ensure high heat-transfer rates and sustain high production rates. On the other hand, an irreversible transfer of heat Q from temperature T_2 to T_1 causes the creation of an entropy $\Delta S_{\text{irr}} = Q(1/T_2 - 1/T_1)$. Minimizing energy degradation thus calls for small temperature differences,

Figure 4 Model of radiative heat exchange between combustion and melting space; q = heat flux per unit hearth area; for meaning of subscripts, see also Figure 2.

for which energy efficiency would be maximum but production rates minimum. In glass parlance, overpull and wastefully low pull represent conditions of maximum temperature differences and minimum entropy generation, respectively. Trade-offs have thus to be found for operating heat exchangers in general [4] as well as glass furnaces in particular [5] (Figure 5).

When looking for such an optimum situation, one takes advantage of the simplifying feature that P_{in} is a linear function of the production rate until overpull is reached and glass quality degrades. This simple relation is obeyed in a surprisingly accurate way as illustrated by data for an end-port, air gas-fired furnace producing Cr-green glass for which the standard deviation of the measurements from a linear fit is only 270 kW (Figure 5b). With a batch containing 40% cullet and a hearth surface of 152 m², the exploited heat H_{ex} amounts to 487 kWh/t and the optimal working point empirically found is $p = 15.7$ t/h. The intercept of the linear fit represents the power input for a zero production rate whereas its slope is the amount of power per unit of production rate. Both parameters are characteristic constants of a furnace. The exploited power P_{ex} and the cumulative losses P_{loss} , see Eq. (6), are also shown in Figure 5b. The values of P_{in} and H_{in} at working point are marked with open circles. The value of P_{ht} (cross) at working point is derived from the flux q_{ht} calculated in Section 3.4. As for the energy demand per 1 ton of produced glass, H_{in} , it amounts to 1164 ± 17 kWh/t at the working point (Figure 5c).

In summary, every furnace possesses a working point representing an optimal compromise for a desired glass quality between production efficiency and energy utilization. Melting in a glass furnace is determined by three characteristic parameters: one is characteristic of the glass batch (H_{ex}) whereas the two others are specific to

the furnace, namely the intercept and slope of the P_{in} line (Figure 5b). This approach allows one to judge the quantitative effects of changes in both batch and pull rate and to compare the performances of different furnaces.

3.6 Reactor Working

The melting space of a glass furnace is a chemical reactor where batch melting and sand dissolution take place, a defined redox state (and, thus, color) is established, and fining and refining are achieved (Chapter 1.3). An important question is thus to know the input–output characteristics of a furnace, i.e. how any change in the batch input affects the exiting melt. In a first pedagogical approach, it is useful to consider an actual glass furnace as intermediate between two reference kinds of chemical reactors, namely the *ideal mixer* whereby the feed is distributed instantaneously over the entire volume, and the *plug flow* which, in contrast, works on a strict first-in, first-out basis (Figure 6). For a real furnace, however, this approach is by far too simple.

In chemical engineering, the ratio between the amounts of a substance introduced by convection and diffusion in a reactor is characterized by the Bodenstein dimensionless number. In glass furnaces, this number $Bo = v L/D$ is about $4 \cdot 10^9$ for an average pull velocity $v \approx 0.4$ cm/s, a path length $L \approx 10$ m, and a diffusion coefficient of $D \approx 1 \cdot 10^{-7}$ cm²/s. For such a large value of Bo , internal diffusion processes do play an important role for local equilibration of concentration differences in a glass furnace, but they may be neglected with respect to the overall response.

Turning to the input–output relationship, we first note that a step input is converted to an exponential output in the ideal mixer whereas it appears as a step output in the

Figure 5 The influence of the pull rate, p , on the operation of a glass furnace.

(a) The different ranges of a heat exchanger clearly distinguished in a so-called chiller plot: η_{ex} , overall coefficient of performance, p , mass flow of the cooling medium, and straight line of the range of normal operation with an intercept $1/\eta_{\infty}$ and slope m . (b) Linear variation of the input power P_{in} as a function of the pull rate p , with an intercept $a = 2523$ kW and a slope $b = 1003$ kWh/t; H_{ex} = exploited heat; open circle: working point $p = 15.7$ h/t; cross: transferred power P_{ht} according to Section 3.4. (c) Typical hyperbolic variation of the overall specific heat demand H_{in} as a function of the pull rate.

Figure 6 Mass input-output characteristics of chemical reactors. (a) Ideal mixer ($m = 1$); (b) plug flow ($m \rightarrow \infty$), the shaded area indicating concentration dissipation by a diffusion process; (c) influence of the parameter m of Eq. (18) on the cumulative response function $F(z)$; $m = 1/2$: dead water flow; symbols: tracer experiment for a container-glass furnace with a melting space volume of $V_L = 131 \text{ m}^3$ operated at a pull rate of 11.7 t/h , hence, $\tau_{\text{nom}} = 28.1 \text{ h}$; inset: differential response function $E(z)$. (d) Sequence of sub-reactors used to model $F(z)$ for the tracer experiments to within ± 0.008 (see Table 1); as $F_1(z)$ accounts for less than 1% of the response, it may be neglected in the numerical evaluation without loss of accuracy.

plug flow. Let then $z = t/\tau_{\text{nom}}$ be a dimensionless time-scale normalized with respect to the nominal dwell time τ_{nom} of the furnace (termed $\tau_{L,\text{nom}}$ in Section 3.1), and $c(z)$ be a normalized dimensionless concentration, $0 \leq c(z) \leq 1$. A step input is thus given by $c(z) = \theta(z)$, with $\theta(z) = 0$ for $z < 0$ and $\theta(z) = 1$ for $z \geq 0$. The output at time z is characterized by the differential and cumulative response functions $E(z)$ and $F(z)$, respectively:

$$E(z) = c(z) / \int_0^\infty c(z) \cdot dz, \quad (16a)$$

$$F(z) = \int_0^z E(z) \cdot dz. \quad (16b)$$

The mean dwell time τ_{mean} is then given by

$$\tau_{\text{mean}} = \tau_{\text{nom}} \cdot \int_0^\infty z \cdot c(z) \cdot dz. \quad (17)$$

For the response function, the use of an extended exponential function (KWW function) is recommended instead of the simple base cases “plug flow” and “perfect mixer.” Thus, the responses of both kinds of reactors may be presented by the common formulae:

$$E(z) = m \cdot z^{m-1} \cdot \exp(-z^m), \quad (18a)$$

$$F(z) = 1 - \exp(-z^m) \quad (18b)$$

and represented in the same way (Figure 6c). For the ideal-mixer and plug-flow reactors, the exponent m is unity and tends to infinity, respectively. An intermediate reactor thus is characterized by $m > 1$ whereas $m < 1$ refers to the so-called *dead water flow* whereby the reactor space is incompletely used because of short-circuit flow through the active volume. This situation yields a fast initial response and a protracted approach to complete replenishment of the volume at $F(z) = 1$, which is a much undesired production feature.

A quantitative assessment of furnace response is a key to an effective management of glass quality during job changes. Such responses can be studied through tracer experiments (Figure 6c) in which a small amount of CaCO_3 in the batch is, for example, replaced by SrCO_3 at $t = 0$ in a step-wise manner and samples of the melt are analyzed for Sr at the exit. For a real container glass furnace, in a first approximation, the output conforms to Eq. (18b) with $m \approx 2.5$. But it is obvious that the protracted approach to $F(z) = 1$ is not well represented in this way. The actual response is modeled by a combination of a finite number of sub-reactors. For this purpose, the response $F(z)$ obtained experimentally is plotted as $W = \ln[-\ln(1 - F)]$ vs. z (Figure 7). In this plot, as a common feature observed with many tracer experiments, the experimental furnace response data display a sequence of three to four linear subregions, suggesting a comparatively simple superposition of few sub-reactors

$$W_i = \ln(-\ln(1 - F)) = m_i \cdot \ln(z) + b_i, \quad (19)$$

Figure 7 Experimental data of $F(z)$ (symbols) presented in a plot $W = \ln[-\ln(1-F)]$ vs. $z = t/\tau_{\text{nom}}$ and straight lines W_i , $i = 1, \dots, 4$ fitted to linear ranges representative of sub-reactors F_i .

$i = 1, 2, 3 \dots$ only (see Figure 7). The slopes of the individual straight lines yield the respective exponents m_i , the intercepts b_i yield the respective dwell times $\tau_i = \tau_{\text{nom}} \cdot \exp(-b_i/m_i)$, and the sub-reactor volumes $V_i = (\tau_i/\Sigma\tau_i) \cdot V_L$. If the slopes increase from $i = n$ to $i = n+1$, then W_n and W_{n+1} correspond to parallel sub-reactors; otherwise, they correspond to sub-reactors in series. The individual functions W_i are superimposed step by step to yield the cumulative function W_{cum} . Ultimately, the modeled response function $F_{\text{cum}}(z)$ is obtained as

$$F_{\text{cum}}(z) = 1 - \exp(-\exp(W_{\text{cum}})). \quad (20)$$

In the example treated here, the data with $F(z) < 1\%$ (sub-reactor 1) may be neglected in the numerical evaluation without loss of accuracy. As a result, the experimental data are represented at an accuracy of ± 0.008 by a superposition of the three sub-reactors 2, 3, 4 in series only. The final result obtained for the case discussed is shown in Figure 6d; the numerical parameters are listed in Table 1.

After the onset of the job change at $t = 0$, the output remains unchanged and the glass quality of the old job is maintained until a critical time $t_{\text{crit}} \approx 6$ hours is reached. A glass of an undefined intermediate quality is then produced until $z = 2.6$, i.e. 73 hours, after which the quality of the new job is again ensured.

4 Modeling of Glass Furnaces

4.1 General Remarks

Thanks to ever-increasing computer power, computational fluid dynamics (CFD) modeling of glass melting

Table 1 Characteristic dwell times τ_i , exponents m_i , and effective volumes V_i of sub-reactors $i = 2, 3, 4$, see Eq. (19), used to model the response function $F(z)$ of a tracer experiment performed on a container-glass furnace with melting space volume of $V_L = 131 \text{ m}^3$ operated at a pull rate of 11.7 t/h, hence, $\tau_{\text{nom}} = 28.1 \text{ h}$; $V_i = (\tau_i/\Sigma\tau_i) \cdot V_L$; F_1 and F_2 in parallel and in series with F_3 and F_4 (see Figures 6 and 7); the critical time for a tracer output $F(z) > 0.01$ is $t_{\text{crit}} \approx 6.0 \text{ h}$; as F_1 accounts for less than 1% of the overall response, it may be neglected in the numerical evaluation without loss of accuracy.

Sub-reactor $n^\circ F_i(z)$	$F_2(z)$	$F_3(z)$	$F_4(z)$
τ_i in h	13.67	19.14	10.10
Exponent m_i	5.66	2.39	0.77
Effective volume V_i in m^3	41.75	58.42	30.83

furnaces has become a powerful tool in the past 20–30 years to simulate operational conditions in glass melting furnaces, forehearths, regenerators, annealing lehrs, etc. The simple 1-D or 2-D models of glass furnaces initially devised in the 1960s [6] have become fairly complex 3-D simulations whose goals are to interpret furnace operation conditions, evaluate alternate furnace designs, and model different operating combinations for combustion processes and electric boosting (or even all-electric melters). The models yield temperatures within the glass melt, the refractory materials, the combustion space, and even for the exiting glass and waste gases. In addition, they calculate the speed (flow) of glass in the melter and working end and – last but not least – they can deal with glass quality, for instance, in terms of level of defects such as bubbles. Corrosion profiles on the bottom or side walls of the furnace can also be investigated in relation to the directions of glass flow close to the refractory materials [7]. In a word, the major advantage of modeling is to yield a wealth of quantitative information on a working furnace that could not be obtained by any other means.

The theoretical bases of finite-element modeling have been presented in Chapter 1.7. It will thus suffice here to illustrate some application to furnaces from the dog-house to the delivery of the glass to the forming process (see [8–17] for more information). Currently, models may have limitations concerning, for example, glass properties at high melting temperatures and especially processes such as batch charging or furnace corrosion. By their very nature, furnace processes are dynamic so that they are subject to such multi-operational influences that cannot always be modeled. In addition, simulations are of course affected by the uncertainties on their input data for density (Chapter 3.5), gas solubility (Chapter 5.5), and especially for strongly temperature-dependent transport properties (Section 4). Particularly for temperatures and glass flows, the two main operational parameters, in

comparison with actual furnace data are of course playing a basic role in assessments of the validity of models. But none of them are readily measured in industrial settings.

For temperatures, difficulties stem from important gradients, which are typically from 10 to 20 K/cm within the refractory walls, and 3 K/cm vertically. Errors in the positions of the measurements can thus be significant and compound the intrinsic 20 K uncertainties of determinations made with either thermocouples (which are in addition subject to significant drift with time and to radiation in the combustion space) or pyrometers (whose output depend on the assumed melt emissivity and can differ for different wavelengths).

Speed measurements in glass flows are still more difficult. With *floaters* made up of buoyant, inert solids, the speed and direction of motion of the melt are directly monitored. Notwithstanding the difficulty of introducing floaters (for example, through holes in the crown), measurements are made difficult by the narrow field of view of peep holes and their lens distortion, as well as by the forces exerted by the flames, which can be strong enough to move a floater counter to the actual glass flow. As made with strontium or zinc, another technique relies on chemical *tracers* incorporated in the batch whose concentrations are measured as a function of time in the glass produced. Portions of the tracer can reveal the shortest or longest residence time in the furnace whereas the existence of several recirculation loops is indicated by as many concentration peaks. The resolution of the method is limited by 0.5–1 hour uncertainties on the time of the tracer introduction and by the 15 minutes typically elapsing between two analyses, which are significant when the minimum residence time in the furnace is 4 hours.

4.2 The Anatomy of a Furnace

Such tracer experiments are readily simulated with CFD (Chapter 1.7), which yield results that can be accurate to within half an hour [18]. Such a precision is illustrated by residence times in a double convection furnace (Figure 8) where the experimental data interestingly appear to smear out the short-term fluctuations revealed by the simulated results.

Even though companies like Corning and Philips determined glass temperature at depth in melters with special thermocouple techniques, few papers have reported comparisons made between measured and simulated temperature profiles. One such study was early made by Philips in cooperation with the TNO Glass Group (Figure 9) for TV screen melting furnaces [7]. Although the differences between the measured and simulated temperatures could locally reach 30 K, there was already very good agreement between both kinds of data [19].

Of particular importance is of course the circulation of the glass in melters during its chemical homogenization (Figure 10). As described in Chapter 1.7, the process is simulated with the well-known equations of continuum mechanics (e.g. Navier–Stokes, differential temperature, and balances of mass and species) along with the phenomenological laws describing the relationship between flux and gradients (e.g. Newton’s law of viscosity, Fourier’s law of heat conduction, Fick’s laws of diffusion), and appropriate mathematical representations of electric heating, bubbling, and other sources of heat and mass transfer impacting the flow of glass.

These models are usually split in two parts. A primary model calculates temperature and flow in the glass and, separately, combustion and radiation effects whereas a

Figure 8 Comparison between tracer residence times in a double-convection furnace measured and calculated by computational fluid dynamics. Long minimum and average residence times of about 10 and 66 hours, respectively.

secondary model takes care of quality by tracing sand grains, bubbles, stones and, in the combustion space, pollutants such as NO_x and SO_x . For a flat-glass melter (Figure 11), an important feature of such simulations is the complex convection pattern whereby part of the melt

Figure 9 Comparison between calculated and measured temperature profiles for a TV screen melting furnace between its bottom at 0.3 m and the top of melt at 1.3 m [18]. K1 and K2: profiles under the yet unmelted batch and after melting, respectively.

comes back from the working end to the melter itself. In more complex simulations, not only the furnace itself but also the associated regenerators may be simulated (Figure 12).

5 Perspectives

As performed within the Technical Committee 21 of the International Commission on Glass (Chapter 9.12), round-robin tests have been valuable to improve modeling tools to the point that they are now used not only for optimizing furnace design in terms of flexibility, quality requirements, or environmental constraints (Chapter 9.7), but also for controlling on line their operation. But the availability of sound mathematical models should not lead to overlook the act that the real outcome of the simulations also strongly depends on an accurate knowledge of glass properties and the operating conditions of the furnaces themselves. When the relevant glass properties are missing, they must be estimated as reliably as possible whereas all boundary conditions are not necessarily known precisely, for instance, when wall corrosion affects the estimated heat losses.

A major challenge consists in the understanding of the competitive roles of heat transfer versus chemical reaction rate as the limiting step in the batch-to-melt conversion. This competition determines the extension of the batch blanket, which, in turn, has a major impact on the entire process. Conventionally, heat transfer is adopted as limiting step, and chemical turnover is considered to follow instantaneously. Depending on the type of batch as well as on the stage of reaction progress, however, chemical turnover may be in control. Understanding this issue would enhance the possibility to predict the extension of the batch blanket in a more reliable way.

Appendix

Solution to the system of Eqs. (15a)–(15d)

The flux q_{ht} is given by

$$q_{ht} = q_2 - q_1 = \sigma \cdot \left[\varepsilon_{\text{gas-melt}} \cdot (T_{\text{gas}}^4 - T_{\text{melt}}^4) + \varepsilon_{\text{crown-melt}} \cdot (T_{\text{gas}}^4 - T_{\text{melt}}^4) \right].$$

The effective emissivity coefficients for radiative heat exchange between gas and melt, and crown and melt, respectively, are the following expressions:

$$\varepsilon_{\text{gas-melt}} = \frac{\varepsilon_{\text{gas}} \cdot \varepsilon_{\text{melt}} \cdot (2 - \varepsilon_{\text{gas}} - \varepsilon_{\text{crown}} + \varepsilon_{\text{gas}} \cdot \varepsilon_{\text{crown}})}{1 - (1 - \varepsilon_{\text{gas}})^2 \cdot (1 - \varepsilon_{\text{crown}}) \cdot (1 - \varepsilon_{\text{melt}})},$$

$$\varepsilon_{\text{crown-melt}} = \frac{\varepsilon_{\text{melt}} \cdot \varepsilon_{\text{crown}} \cdot (1 - \varepsilon_{\text{gas}})}{1 - (1 - \varepsilon_{\text{gas}})^2 \cdot (1 - \varepsilon_{\text{crown}}) \cdot (1 - \varepsilon_{\text{melt}})}.$$

Glass Cullet: Sources, Uses, and Environmental Benefits

Nicola Favaro and Stefano Ceola

Stazione Sperimentale del Vetro, Venice, Italy

1 Introduction

Glass is one of the more common materials in daily life. It is used in glass containers for food and beverages (Chapter 1.5), windows for buildings (Chapter 9.1) and all kinds of vehicles (Chapter 9.2), fibers for insulation (Chapter 9.3), continuous fibers for reinforcement (Chapter 1.6), screens of electronic displays (Chapter 6.10), household products, etc. Among a great many other advantages, it can be considered to be a “permanent material” [1] as it can in principle be recycled indefinitely to produce new glass without significant loss of material, which means that 1 kg of small glass fragments called cullet can be melted to produce 1 kg of new glass. This feature makes glass one of the best materials for the development of the circular economy concept with a low consumption of new raw materials and a reduced exploitation of natural resources.

In 2007, the world glass production was estimated to be 115 million tons, the European Union (EU) representing 32 % of the total [2]. The global market for container glass packaging accounted for 46 million tons in 2012 [3] and for flat glass (buildings, automotive mainly) for 52 million tons in 2009 [4], thus representing together almost 85 % of the worldwide production. The remaining 15 % went to the production of tableware, glass wool, continuous fibers, and specialty glass. Such data are estimates and should be taken with caution because other reports provide different figures. But such differences do not matter at all for the purpose of this chapter, which is to deal with the environmental issues raised by these large quantities, particularly in terms of waste management.

In this respect, the hierarchy of options for waste disposal (Figure 1) set by the Waste Framework Directive 2008/98/EU [5] must be taken into account. Any option depends on financial, social, and environmental considerations; for glass, however, it is well accepted that reducing the production of waste while increasing reuse and recycling should be the preferred option. But if reuse is a priori considered to be the best option from an environmental point of view, it is facing real limitations caused by the difficulty of implementing it in practice. The reuse of empty containers is, for instance, economically and environmentally advantageous only if both product and brand are part of a local market, as is the case of local milk or beer distributors. But it is not viable when products either have long end of life, as is the case of windows for building, windmills, etc., or cover global-, national-, or regional-scale production as in the wine, beer, mineral water, food, or automotive industries.

In contrast, the recycling or recovery of glass after transformation into cullet can potentially be applied everywhere for the production of new articles. In such cases the end-of-life glass pieces need to be collected and delivered in specialized facilities to be treated through grinding, cleaning, sorting, etc., before being supplied to glassmakers. The key advantages of recycling or recovery is the reduction of waste disposed or dispersed as litter, as well as the reintroduction of secondary materials back into the economy.

The sources of recovered glass for glass recycling mainly come from container glass packaging and flat glass, as they account for the majority of glass produced worldwide and are relatively uniform in terms of composition, being constituted by soda-lime-silica glass. The present chapter will thus focus mainly on glass cullet recycled from these sectors. The different categories of cullet will be first presented. The problems raised by glass recycling will then be briefly reviewed. Following a

Figure 1 Hierarchy for glass waste.

discussion of the current cullet sorting technologies, the nature of the rejects, their disposal, and the environmental benefits of recycling will finally be discussed.

2 Basic Features of Cullet

2.1 Categories

Cullet depends on the type of industry considered and on the availability of a collecting and reprocessing system. Its sources can be either rejects produced during manufacturing of flat or container glass, continuous fibers, glass wool, special glass, tableware, etc., or end-of-life articles such as bottle and jar containers, TV screen, windows, automotive glass, tableware, etc.

In spite of this diversity, glass cullet can nonetheless be split in two main categories depending on its source. The *internal* cullet is mainly composed of defective products rejected during the manufacturing process as a result of quality control, transition between two different kinds of production (color change, parameter modifications, etc.), or secondary process rejections (cutting, grinding, etc.). As to the *external* cullet, it is waste glass collected and/or reprocessed with the purpose of recovery or recycling.

External cullet can itself be divided further in two types:

(i) *Pre-consumer* (industrial) cullet resulting from the manufacturing of glass products, which is not internally recycled and leaves the facility as waste; this material can be recycled in another facility for the production of glass, reused for other specific applications (such as road filler, aggregate, etc.), or disposed in landfill.

(ii) *Post-consumer* cullet, produced from glass products originating in the consumer market, including glass bottles, jars, tableware, windows, vehicle glazing, etc.; this material can be recycled into new products after appropriate collection and treatment process and/or reused

for different purpose than production of new glass, for example, as road or aggregate filler.

The relative amounts of pre- and post-consumer cullet vary considerably depending on the industrial structure and waste policy in place in the specific country. The latter cullet nonetheless predominates, especially where a collection and recovery system is available, followed by flat glass pre-consumer cullet. Reflecting much the much lower quantities produced, the smallest amounts are pre-consumer glass cullet from mineral wool, continuous filament fiber, special glasses, etc.

2.2 Glass Waste: Some Comparisons

Municipal solid waste (MSW) is locally determined by the degree of development and industrialization, energy sources, climate, and also social and cultural behavior as documented by a World Bank report that illustrates the variability of its generation and composition [6]. It comes as no surprise that the amount of MSW generated per capita is higher in developed countries and urbanized areas where the proportion of man-made materials such as plastics, glass, and aluminum is in addition higher in comparison with biogenic products such as food or garden and wood waste. The same World Bank report gives data from which the increase of waste glass from 2012 to 2025 in MSW can be estimated for four categories of countries grouped according to their relative wealth (Figure 2): lower income (Vietnam, Serbia, Ethiopia, etc.), lower middle income (China, India, Turkey, etc.), upper middle income (Uruguay, South Africa, Mexico, etc.), and high income (United States, Germany, Japan, etc.) [6].

Although global estimates have been made for the production of waste glass, analogous figures are lacking for current or projected rates of recovery worldwide. As representative examples of two widely different systems, Europe and the United States will be selected here to contrast a high/low recycling rate along with a well-established/developing policy for glass waste collection and recycling. In preamble, however, it should be noted that high reuse or recycling glass rates can also obtain in countries lacking specific environmental policy or collection systems. In many developing countries, informal waste pickers at collection points and disposal sites recover indeed a significant portion of discards.

A specific legislation has constrained member countries of the EU to adopt policies for the collection, treatment, and recovery of packaging waste [2]. It specified a target of 60 % cullet recycling by 2008, which is actually to be increased to 85 % by 2030. As a result, Europe probably is the region with the highest recycling rate for glass. As

Figure 2 Estimation of waste glass generated by municipal solid waste.

split into six different sectors, the amounts of glass produced and of waste generated, collected, and recycled are listed in Table 1. Of this waste, pre- and post-consumer cullet represent 25 and 75 %, respectively [7]. For container glass the data of Table 1 mainly refer to post-consumer waste, whereas the opposite holds true for flat glass and tableware. As for the amount of cullet collected and recycled from mineral wool and continuous fibers, it is negligible compared with that of container glass.

Post-consumer container glass thus is the main source collected, processed, and recycled to produce new container glass for the food and beverage industries. The proportion of recycled container glass nonetheless remains strongly impacted by national waste legislations as illustrated in Table 2 where the EU-28 recycling rate in 2014,

Table 1 2007 European statistics for glass cullet. End-of-waste (EoW) criteria for technical proposals (million tons) [7]. Figures expressed in Million of tonnes.

Glass sector	EU production	Waste glass generated	Waste glass collected	Waste glass recycled
Container glass	21	17	11	8
Flat glass	9.5	5.1	2.9	2.9
Tableware	1.5	0.8	0.5	0.5
Mineral wool	3.7	2	NA	NA
Continuous filament fiber	0.7	0.4	NA	NA
Special glass	1	0.5	0.45	0.4

calculated as the ratio between the total amounts of glass recycled and collected, varies from 21 % (Greece) to 102% (Sweden). The average value is 74 % (70% if Turkey, Norway, and Switzerland are included), seven countries having already outdone the 2030 target of 85 %, namely, Austria, Belgium, Denmark, Germany, Luxembourg, Slovenia, and Sweden (or nine if Norway and Slovenia are included). Potentially higher quantities of post-consumer cullet could be recovered from end-of-life vehicles (ELVs), electrical and electronic equipment, and building demolition. Such materials are not yet well regulated in Europe, however, and the recycling industry is still facing cost issues related to the collecting system and quality of the final materials.

Estimates of the total amount of glass produced in 2013 in the United States and of the relative amounts recovered and discarded are listed in Table 3 [8]. Although the amount of glass containers recovered from MSW increased from 2.6 to 3.2 million tons between 2005 and 2013, it represents a fraction of only 27 % of the total glass made and 34 % of the container and glass packaging produced. Compared with those mentioned for the EU, these numbers are thus very low even though the notion that glass is a recyclable material is well established in the United States where there is widespread access to glass recycling and where the recovered cullet is used to make new glass containers and other products such as insulating fibers or aggregates for drainage and roadbed applications. This contrast is readily explained in terms of differences in infrastructures and public policies: whereas landfill costs are much lower in the United States, distances to remanufacturers are longer, and collection systems are not subsidized by industrial consortiums.

2.3 Cullet Applications

The possible uses of pre- and post-consumer cullet from different sources are many although the proportion of recycled material can be really high only for containers and insulating fibers (Table 4). Among the main glass products, containers are in general those for which raw material requirements are the less stringent and for which production costs must be as low as possible to face a stiff

Table 3 Glass recovered and discarded in 2013 in the United States. Figures expressed in Thousand of tonnes.

Glass sector	Production	Recovery	Discard
Durable goods (furniture, appliances, electronics, etc.)	2280	Negligible	2280
Glass containers	9260	3150	6110
Total glass	11 540	3150	8390

competition from other materials such as plastics or aluminum. The majority of the cullet recovered is thus recycled into new colored glass containers. In Europe, some manufacturers are even able to use more than 90 % of mixed colored and colorless cullet. Production of colorless containers is in contrast limited because high-quality cullet has to be supplied either by distinct collecting systems or by secondary color sorting processes. Likewise, the proportion of cullet from external sources used to make flat glass is as low as possible in view of the color stability and lack of defects required. Some experiments are nonetheless made in Europe to produce flat glass using 30% of recycled clear, low-iron glass.

Recycling of cullet is impacted at the national level not only by specific legislation imposing a recycling rate target but also by the availability of supply chains providing glassmakers with a continuous delivery of cullet at an acceptable quality and cost. When such system are not available, or the cost of cullet is higher than that of the mineral batch to be replaced, other secondary market applications for glass cullet have to be found. In general, these do not require as strict quality criteria as for glass-making. Cullet then becomes less expensive than usual raw mineral materials for making abrasives or ceramic sanitary ware, fluxing agents in brick manufacture, or fillers in water-filtration media and in civil works.

3 Glass Recycling

3.1 Container Glass

Pre-consumer cullet can be collected directly from the producing plant. At the country level, specific legislations define what waste is and the procedures to be followed accordingly. Post-consumer cullet can be collected in two main ways, either as glass only in the so-called bottle banks or otherwise as glass mixed with other dry recyclables such as metals and plastics. Mono- and multi-material collection systems have their own advantages and drawbacks. Especially when glasses of different colors are collected separately, mono-material systems provide a higher-quality cullet with a lower fraction of impurities.

Table 4 Origin and possible applications for cullet.

Origin of the cullet	Possible application	Potential range of recycling
Container glass, glass packaging	• Container glass (excluding flaconnage, borosilicate container, and high-quality tableware)	20–90 %
Flat glass	• Insulation mineral wool • Container glass • Flat glass	10–40 % 20–90 % (mainly colorless glass) 20–30 %
Insulation mineral wool	• Insulation mineral wool	20–60 %
Continuous filament glass fiber	• Continuous filament glass fiber	10–30 %
Tableware	• Container glass (excluding lead crystal glasses) • Tableware • Insulation mineral wool	20–90 % 10–20 % internal cullet 20–60 %

Table 5 Scrap from mono-material collection in bottle banks (unpublished SSV data).

	Percent of material	Percent of rejected stream after treatment	Percent of glass lost in the different stream
Metals	0.6	0.9	0.3
Waste	1	1.9	0.9
Ceramics	0.15	3	2.85
Glass	98.25	94.2	
Total	100	100	4.05

Table 6 Scrap from multi-material collection in bottle banks (unpublished SSV data).

	Percent of material	Percent of rejected stream after treatment	Percent of glass lost in the different stream
Metals	5.6	7.4	1.8
Waste	19.4	25.1	4.1
Ceramics	2.2	20.3	18.1
Glass	72.8	47.2	
Total	100	100	25.6

Typically the proportions of rejects, i.e. non-recyclable residues present in the collected material, are 1 and 12–15 % for mono- and multi-material collection systems, respectively. But the former are more costly than the latter, especially if color separation has to be made, and are more complex to manage for households in terms of both handling and sorting space.

Estimates of the amounts of scrap mixed with glass have been made for both mono- and multi-material collection systems (Tables 5 and 6). The values represent only rough estimates as they strongly depend on the willingness of the citizens to follow the recycling rules and on the posttreatment process applied to separate the different materials and to remove impurities. The figures nonetheless show that in multi-material collection the amount of cullet lost with the other materials (metal, waste, and opaque bodies) is definitely higher, reaching 26% of the total input.

3.2 Flat Glass

Almost 80% of flat glass is used for building application, 15% for vehicle glazing, and the rest for other purposes [9]. In any country recycling of flat glass is thus strongly

impacted by the existence of specific environmental policies and, in particular, of legislation on construction and demolition (C&D) waste and/or ELVs to be implemented in recycling programs.

Although flat glass currently represents only 0.4% of C&D waste [10], this value is expected to increase through the increasing use of glass as a structural element in architecture (Chapter 9.1). That flat glass is such an insignificant part of a building makes of course its recycling especially difficult given that the removal of glass panels prior to demolition is not economically viable. Flat glass is thus absorbed into other streams, so its amounts recovered from C&D remain low. But new regulations are under discussion worldwide to promote its recovery and produce cullet for different applications.

For ELVs the dismantling processes focus on the recovered metal, which accounts for 75 % of a car mass. Glass represents only 3%, the remaining 22 % being a complex heterogeneous waste that contains many different plastics (thermoplastics and thermosets), elastomers, foams, remaining metals, wood, or textiles. Recycling of such a heterogeneous stream is currently neither technically nor economically feasible, so landfilling prevails. Again, national policies will be enacted to recover more material.

Figure 3 Cullet treatment process. CSP, rejects of ceramic, stones, and porcelain.

As for glass, its removal before shredding will then be mandatory as cullet cannot be recycled once contaminated with metal scrap.

4 Separation Technologies

4.1 Treatment Systems

Prerequisites to obtain a stable, clean, and ready-to-furnace cullet are (i) to avoid the presence of all possible polluting materials harmful for the final glass container such as ceramics, stones, glass ceramics, and metals, (ii) to eliminate fragments of lead crystal glass, (iii) to achieve a sharp grain size distribution limiting the volume fraction of fines, and (iv) to eliminate organic materials such as paper, wood, and plastics. If fulfilled, these conditions imply that the cullet is no longer waste but a true secondary raw material. In practice, the details of the process may vary from one setup to another. The sketch of Figure 3 is only a general description of one possible process designed to clean cullet. For some companies the order of the operation can vary, depending on the type of incoming material and internal business decision.

The input material comes from municipal waste dry recyclable. The output can be either mixed cullet or flint (colorless glass) cullet produced by color separation plus the remaining cullet that have been separated from the flint. In fact color separation is usually applied to mixed cullet to get white (colorless) or half-white cullet, whereas the rest is a mixed cullet with a lower flint fraction. If managed correctly, the treatment results in a final mixed cullet product that is virtually clean from ceramic, stone, plastic, and metallic contaminants (Figure 4).

Figure 4 Mixed glass cullet.

4.2 Sorting Machines

Different detection systems are used to remove the fragments of undesirable contaminants. Broadly speaking, there are four types of such systems: (i) visible near-infrared detection [11] to remove glass ceramics, (ii) visible light detection to remove opaque material (CSP) or to separate colors, (iii) UV fluorescence detection for the removal of lead-glass fragments, and (iv) X-ray fluorescence detection for the removal of

Figure 5 Sketch of a typical sorting machine for cullet.

material with a specific composition, especially useful for lead-glass fragments.

These machines in general work continuously by letting the cullet flow through the detection system, which triggers a subsequent array of air blows that are activated when some contaminating material is identified (Figure 5). Actually even the highest-quality cullet is not completely free from contaminants because various factors make the efficiency of removal of these machines lower than 100 %. These are (i) the condition of material because the ability of a system to recognize an undesired material depends on cleanliness of the glass (and, thus, on surface humidity or on the amount of contaminant attached to the fragment); (ii) the type of material because the waste is not always processed at the same rate and may come from different places and because the sorting machine must be calibrated accordingly as the quantity and nature of the contaminants can differ; (iii) the air blow, which is not selective and does not remove only the undesired contaminant, but also neighboring glass fragments; and (iv) the stream effect, caused by the fact that the air blow is not instantaneous but has a certain finite duration so that other fragments in the tail of the target can be erroneously removed even with the best synchronization. Because of these effects, the rejected material can thus contain “good” glass, whereas the clean glass can still contain some contaminants.

4.3 Rejects

All operations applied to clean out multi-material to obtain glass cullet necessarily yield a certain amount of rejects, which still contain a certain amount of “good” glass. Hence, it is useful to describe also briefly the various types of rejects and then to review possible strategies for recycling of rejects according to the appropriate workflow (Figure 3).

Organics comprises paper, wood, and plastic (hard and soft package), along with residues of adhesives (for labels), sealants (PVB, rubber), oil, and grease. Depending on the

type of glass to be recycled, these are taken out differently. If color separation is included in the workflow, sealants (e.g. PVB, rubber) are eliminated by dry methods only for the flow of half-white glass [12].

Small pieces of paper, fragments of wood, fabrics, residues of adhesives, sticking oils, and greases are rarely washed out but simply burned at a suitable temperature (about 600 °C). Big plastic pieces are often taken out by visual and manual sorting, whereas small, loose fragments are usually eliminated together with glass fines by sieving.

Scrap of metals such as iron, steel, and aluminum are taken out from multi-material waste in several steps. Often the material delivered to the collection sites is pretreated with magnets and electrostatic systems to take out big pieces of magnetic metals and aluminum cans, respectively, with the added advantage that aluminum is itself another valuable recyclable for the metal industry. After this pretreatment the material is more suitable to be processed by sorting machines. During this subsequent flow, a second round of magnetic and nonmagnetic separation is performed to remove metallic contaminants as much as possible. This material is usually sent to companies possessing a technology suitable for waste metal processing so as to provide clean metal scrap to be reused for metal processing.

Ceramics, stones, and porcelain (CSP) designate all inorganic contaminants that cannot be melted in a glass furnace, such as pieces of fireclay, rocks, bricks, and ceramic and porcelain fragments erroneously discarded in the multi-material collection bins. If present in a glass batch, these materials may melt incompletely in which case they give rise to *stones* (Chapter 1.2), which are a cause of rejection of the glass produced (Chapter 1.2). These refractory contaminants are thus usually removed with optical sorting systems that discard opaque fragments and clear out the cullet flow. The reject usually contains a large quantity of glass, which is unfortunately lost in the workflow if a recovery strategy is lacking.

Glass ceramics often comes from cookware, dismantled oven windows, and cooktops. These materials are hardly distinguishable from normal glass, and the technology of sorting, even if it is already applied to the treatment workflow, is not as mature as the others.

Fines are usually removed from the workflow first through sieving of the pretreated material at some size cut to facilitate the removal of glass contaminants by the sorting machines. This size is determined by the efficiency of the sorting machine itself, which actually can work from 5 to 8 mm size upward. Below this size, the removal of CSP contaminants at the required quality level cannot be guaranteed with the removal efficiency of the most widely used technology.

4.4 The Particular Case of Lead Glass

There are different forms of legislation in place, as example in the EU as well as in the United States, which set specific limits for heavy metals (mercury, cadmium, lead, and chromium IV) in packaging and packaging waste. The amount of mercury, cadmium, and chromium IV in glass containers is negligible because these elements are present neither in the raw materials nor in the glass cullet recycled. However, lead can be detectable as it can be introduced in the glass furnace through the cullet stream, which can contain small amount of crystal glass fragments recycled together with the soda-lime-silica glass containers. To be in compliance with the specific legislations, the removal of lead-glass fragments is mandatory, especially when the recycling rate is quite high.

Lead-glass fragments are mostly scrap glass from cathode-ray tubes (Chapter 6.10) mixed with small amounts of tableware crystal glass. Because EU regulations have set an upper concentration of 200 ppm Pb in glass, efforts have been made to develop technologies for sorting out lead-glass fragments from the cullet workflow. But some cullet is inevitably rejected along with lead fragments and is lost as it is usually sent to a suitable hazardous waste dump. Great care must be taken in cullet cleanliness as well, since a fragment of polluting lead glass may not be removed from the stream if it is not recognized by the sorting detector, as it might happen when the glass fragments is covered by mud.

The lead content of rejected lead glass is so high that its direct reuse in glass industry is not advisable. Different processes are potentially applicable to dispose of them, but they are in general not economically sustainable. A chemical process devised [13] to recover a material possibly suitable for the glass industry and other types of production involves the solubilization of the glass scraps in a caustic environment (NaOH) and the separation of metallic lead with an electrochemical cell. The solution is then treated to recover the sodium silicate and possibly to reuse also the insoluble silicate (of Ca, Mg, etc.) in the glass industry. The process has been devised for CRT scrap glass whose PbO content is about 30 wt %. But the economic viability of this process remains to be assessed for the sorting-machine cullet whose PbO content is about one order of magnitude lower.

4.5 Reject Minimization

The fraction of rejects generated depends on the type of material processed, the condition of the material (presence of mud, water, paper), and the final quality desired. In this respect, the upstream cleaning steps of plastic,

scrap-metal and fines removal, organics burning, and washing are most important to optimize the efficiency of the downstream sorting machines and, thus, to minimize the improper rejection of cullet and the amount of waste to be landfilled. The sorting technology can by itself make a difference. The efficiency of these machines is related to the flow rate, the cleanliness of incoming cullet stream, and the dimensions of the fragments to be removed. As actually applied in the most modern treatment plants, average flow rates of about 20 tons per hour give a consistent stream of processed cullet to feed the glass container industry. In this situation the sorting machine could reject a certain quantity of “good” cullet through the jet stream effect, lowering the recycling yield of the treatment plant and, in consequence, that of the overall treatment system.

The minimization strategy in this case relies on multi-blow arrays and short blow pulses to reduce the jet stream effect and, thus, the reject of good cullet. Dirty cullet would cause false-positive reject, that is, a glass fragment could be recognized as pollutant to the sorting machine, in the case of CSP removal (opaque appearance). For UV sorting of lead glass, the presence of pieces of paper on the fragments could cause the reject as paper is usually active under UV light. In this case the minimization strategy mainly relies on the cleanliness of the incoming cullet stream, which depends on the initial condition of the material and on the efficiency of the operations performed upstream.

5 Miscellaneous

5.1 Cullet Quality

Nowadays cullet is widely used in the container glass industry thanks to its beneficial effect on environment and process economy. These benefits were and actually are the driving force for the continuous improvement of the quality of the collection and treatment systems. Good cullet available to the glass container industry leads to a high efficiency (low rejects, low added costs) and a high quality in terms of both added value and color matching and stability, for which the demands of bottling and packaging firms are stringent.

Good cullet comes from up-to-date and efficient treatment plants, which apply the most modern technologies for sorting and the most efficient strategy for the recovery of rejects. In addition, the efficiency relies also on the type of input material: the collection system could be multi-material (glass, plastic, and metals), single material (glass only), or even color separated.

5.2 Redox and Color

Even under the most favorable conditions, cullet carries residues of sticking papers, glue, oil, and grease. With average utilization levels of about 60–65 wt % of the total batch and peaks of 90–95%, a 0.5 wt % organic content could be detrimental for the melting kinetics in the furnace and color stability of the glass produced. Acting as reducing agents, organics change the redox state of the melt and, thus, the equilibrium between Fe^{2+} and Fe^{3+} that determines glass color (Chapter 6.2), giving rise to quality problems when causing deviations from the optimum range. In addition, the melting kinetics of the batch may slow down as a result of foaming in the furnace (Chapter 1.1), whereas the presence of bubbles or stones leads to an increase of rejection rates.

The introduction of color sorting machines has had a positive impact on the amount of cullet recycled, but some unexpected contraindications have been noted. The redox [14] state of the cullet fed depends on the relative amounts of the different colors. Usual mixed cullet containing flint glass is no longer widely available on the market, and the colored cullet obtained after flint cullet separation is a mixture of green and amber. This change in composition and color leads to a different product. When used for the production of colored glass, small variation, for example, can modify the batch redox number (a measure of its reducing power; cf. Chapter 1.3, [15]), causing color instability, especially for reduced glass such as amber and UV absorption glass (UVAG).

5.3 Possible Reject Valorization

Valorization of rejects must be evaluated in the analysis of the type of contaminant that could harm the final product, the glass container. Different types of reject require different recovery strategies. As an example, CSP fragments of more than 8 mm in size cannot be digested completely in a glass furnace (Chapters 1.2 and 1.3), which is in about 20 hours of melting at about 1450 °C. Their remains are then found as stones in the final glass containers, which are discarded by the in-line control before palletizing. A possible strategy for the recycling of CSP for glass container production is grinding, whereby fragments reduced to a size millimeter are easily digested by the melting furnace. This fine material obtained from grinding of CSP rejects and often fines is called glassy sand. To produce it the CSP reject is usually cleaned from very big fragments of material still present, mixed to the fine fraction, eliminated upstream, and grinded together with a lower granulometric profile.

Another possible use for CSP and fines reject is as road substrate, especially for grain sizes lower than 2.36 mm

[16]. Coarser sizes do not give the appropriate shear strength, which make these rejects unsuitable for geotechnical engineering applications. Other possible uses of fine-grained cullet reject currently under study concern cement, fireclay, and concrete.

6 Environmental Aspects

6.1 Cullet Life Cycle in the Light of Circular Economy Concept

In recent years policy makers have been increasingly involved in defining strategies and political and legal actions to implement and enforce the concepts of sustainable development and circular economy. The goal is to ensure a safer future where the challenges of resource scarcity, environment pollution, climate change, etc., can be kept under control or even overcome. Within this framework, a “responsible” management of resources is promoted through minimization of the waste streams sent to landfill disposal and incineration and preferential usage of resources that are effectively renewable or indefinitely recyclable over time.

As already stressed, glass is one of the best materials in terms of circular economy as it can be considered as a *permanent material*, which can be theoretically recycled an infinite number of times to manufacture a new glass article without significant addition of mineral raw materials. The percentage of glass cullet substituting mineral raw materials can reach up to 95% of the total bath composition. The main issue for such target is the availability of an efficient collection system, cullet treatment process, and market.

6.2 Environmental Benefits

Given a typical batch composition for a soda-lime-silica glass (61.9 wt % silica sand, 17.8 soda, 11.3 marble, 5.5 dolomite, 1.8 feldspar, and 1.7 others), one readily estimates that 1.2 tons of raw materials is saved per ton of recycled cullet used. Out of this 200 kg difference, about 150–160 kg represents the amount of CO_2 released upon heating and melting by carbonate raw materials such as soda, marble, or dolomite (the remaining weight is the water added or present in the batch and small amount of sulfates and organics). In addition, less energy is needed to remelt cullet than to melt a batch of raw materials. The difference amounts to 2.5 % of the total glass-melting energy consumption for each 10 % cullet added to the batch [17].

Besides, the use of cullet allows significant savings in terms of the “indirect” energy spent for the extraction,

production, and transportation of raw minerals. When the energy needed for the collection, treatment, and transportation of cullet is also taken into account, the net benefit is also clear although it of course depends on the assumed energy consumption for the extraction and production of the raw materials, on the origin and distribution of this energy, and on the type of system adopted (i.e. gate to gate, cradle to gate, cradle to grave, or cradle to cradle). For the most significant cradle-to-cradle case, a comprehensive life-cycle assessment (LCA) has been made by FEVE [18], the European Container Glass Federation, together with GPI, the US container glass trade body. For a whole cycle returning a container to its original condition after use, the result is that one ton of recycled cullet gives rise to a saving of 670 kg of CO₂ by comparison with the use of extracted raw materials.

The use of cullet thus translates into considerable environmental advantages in terms of reduced consumption of mineral resources, less intensive mining activity, lighter CO₂ footprint, lower energy consumption, and reduced amounts of materials to landfill or incinerated. And these advantages are especially noteworthy as glass can be recycled indefinitely.

7 Perspectives

Beyond the Paris Agreement and incentives for sustainable development, the main commitment in the future would be the limitation of the use of natural resources and the lowering and containment of CO₂ emission. For sectors with high energy and CO₂ footprint such as the glass industry, there is no choice but to continue and to increase the use of recycled glass: these goals can be reached by a strong, common commitment of the different entities involved in the circular economic frame of glass.

The glass industry must improve the technological control of the process, being able to cope in almost real time to possible fluctuations in cullet quality and to increase the use of secondary raw material obtained from the cullet reject valorization. Treatment plant must apply the best reference techniques for glass cleaning and sorting and find strategy for convenient process design. Citizens must be aware of the impact of their waste, being responsible on the destination of possible recyclable material. Authorities must give definite leverage to industry for making investment for coherent innovation possible toward a more closed and sustainable circular economy and by making these goals known to the general public.

An increasing use of cullet in the whole developed world is unlikely given the already high level of recycling.

Probably only in the United States and Russia is there room for consistent growth if suitable actions are undertaken to activate a sustainable system. But developing countries, as well as BRICS, should from the beginning apply the best practices to limit the overall environmental impact of their growing economies.

9.10

Immobilization of Municipal and Industrial Waste

Soraya Heuss-Aßbichler¹ and Athanasius P. Bayuseno²

¹ Section of Mineralogy, Petrology and Geochemistry, Department for Earth and Environmental Sciences, Ludwig-Maximilians Universität München, Munich, Germany

² Centre for the Waste Management, Department of Mechanical Engineering, Diponegoro University, Semarang, Indonesia

1 Introduction

Waste disposal is an issue as old as urban life. With the invention of the city in Mesopotamia more than five millennia ago, not only did waste become spatially concentrated through marked increases in population density, but the economic growth made possible by the division of labor caused the amount of waste produced to rise correspondingly. By far the simplest way to dispose of garbage long remained to throw it away, hence the regular elevation of the ground surface observed in many old cities. If such practices have since then proved a boon for archaeologists thanks to the great many artifacts (glass and ceramics, in particular) that can be recovered underground, the need to limit garbage accumulation was recognized early. To reduce the filthy smell of the Parisian mud stirred by horse carriages, the French king Philip August (r. 1180–1223), for instance, ordered in 1184 the streets of the city to be paved with “hard and resistant cobblestone,” a decision that none of his predecessors had taken because of the difficulty and high cost of the work [1]. But it would take a very long time before garbage became actually collected so that in the eighteenth century chroniclers were still complaining about the dirtiness of European cities. This awareness was enhanced in the nineteenth century through recurring episodes of epidemics like cholera and understanding of their microbiological causes. Although waste began to be regularly collected, it was in general simply dumped in growing volumes at the outskirts of the expanding cities.

Toward the end of the nineteenth century, the idea to incinerate waste was thus formulated to reduce its volume by 90 % and to eliminate safely any disease-carrying agents. The first municipal waste incinerator (MWI) was installed in Nottingham (England) in 1874. From 1887 to 1908, about 200 incineration plants were constructed in Europe in spite of the resistance met among local people because of bad smell and dust production. When water-steam networks were developed in the late nineteenth century, garbage became one of the energy sources exploited, but cheap energy and concerns about emitted pollutants later on caused operation of incineration plants to meet with difficulties. In the 1970s, the issue came back to the fore as a result of the energy crisis, so new municipal waste combustion plants were built to produce heat for the generation of steam and/or electricity. At the same time strict regulations were enacted to limit the emission of pollutants such as heavy metals and polychlorinated dibenzodioxin and dibenzofuran (PCDD/PCDF).

Modern incineration plants are also known as *mass-burn incinerators* or *waste-to-energy plants* (Figure 1). With a typical consumption of 4500 m³ of air per ton of waste, most of the organic matter is oxidized and released into the atmosphere in the *flue gas* as H₂O and CO₂. After combustion three types of residual solid products are produced, whose nature and properties vary considerably with the composition of the waste and also with the combustion process itself: (i) *bottom ash*, which simply accumulates on the firing grate of the combustion chamber, is mainly composed of silicate glasses or minerals, and typically represents about 10 vol % 25–35 wt % of the original waste; (ii) *boiler ash* and *fly ash* (~3–6 wt %), which condense from the fumes during cooling as glass and other compounds such as salts; (iii) *air pollution control (APC) residues*

(~1–5 wt %), mostly salts and dust (dry APC) or sludge (wet APC), which are eventually retrieved from the flue gas at the end of the process.

The reason why glass phases are major components of both bottom and fly ash is simply that Si and Al are themselves major elements of the initial waste. Particular attention will thus be paid to these glasses in this chapter, in relation to the other components of the residues with which they interact in various ways. And because environmental regulations keep becoming tighter, the long-term stability of these materials will also be dealt with in terms of complete vitrification and leachability of the residues. From sewage sludge to medical and electronic waste, a variety of other waste products will be finally considered because in each case vitrification is a possible solution for safe immobilization. The example of coal will illustrate the importance of the issue since the amounts of coal burned are very high. A single electric plant produces more than 125 000 tons of ash per year.

2 Municipal Solid Waste Incineration Residues

2.1 Conventional Combustion Plants (Grate Firing)

Municipal solid waste (MSW) is commonly called *trash* or *garbage* in the United States and *refuse* or *rubbish* in Britain. It is an extremely heterogeneous material whose

composition varies seasonally and differs from country to country owing to differences in lifestyles, waste treatment, and collection and recycling systems. In developed countries, it is mainly composed of kitchen waste, paper, plastics, metals, and other materials such as textiles, leather, rubber, e-waste, and various pigments often made of heavy metal oxides. It also includes inorganic materials not only as conspicuous glass, ceramics, concrete, or stone fragments but also as “hidden” components present at fractions of up to a few 10 wt %, for example, in plastics in which *fillers* (calcium and barium carbonates and sulfates, mica, or glass) are introduced to improve mechanical properties (Chapter 8.8) or to lower the amount used of the more expensive polymer and in paper and cardboard whose *coatings* (with kaolinite $[\text{Si}_2\text{Al}_2\text{O}_5(\text{OH})_4]$, talc $[\text{Si}_4\text{Mg}_3\text{O}_{10}(\text{OH})_2]$, calcium carbonate, or titanium dioxide) ensure the smooth surfaces needed for high-quality coloring or printing.

Municipal waste has a calorific value for incineration ranging from 8 to 12 MJ/kg, a high quantity of kitchen waste lowering this value. Although combustion is stipulated to take place at least for 2 seconds at 850 °C, temperatures around 1000 °C are customarily favored to ensure complete burn off and to reduce the total organic carbon (TOC) content to less than 3 wt %. The manner in which metals partition upon combustion between bottom and fly ashes depends on their own physicochemical properties and on those of the compounds they form. Heavy metals with a low vapor pressure are retained in the bottom ash. Those elements with a high vapor

pressure and a low boiling point are expected instead to be transported with the flue gas so that they are enriched in the fly ash and/or APC residues. In consequence, Si, Al, Fe, and Cu mostly accumulate in the bottom ash, whereas Pb, Zn, Hg, Cd, and As have a higher tendency to be transported by fly ash. Overall heavy metals may represent up to 10% of the total mass of the ash.

2.2 Bottom Ash

Also called *grate ash*, *slag*, or *clinkers*, bottom ash is commonly wet discharged through periodic quenching in a water tank. These ashes are in general a mix of very fine, gray, porous material and larger chunks of glass, ceramics, metallic fractions, gravel, and rock (Figure 2). The main grain size of fresh bottom ash varies between sand (0.063–2 mm) and gravel (2–63 mm). Approximately 30–40 wt % of the bottom ash consists of fine-grained particles (<2 mm), 30–40 wt %, which vitrify and/or sinter upon combustion of the waste, 10–20 wt % represent incombustible matter (e.g. rock, ceramic, and glass), and about 10 wt % represent metals, usually Al, Fe, and Cu. A small part (<1 wt %) of the waste, including paper, plastics, and wood, may pass the combustion procedure unburned.

The dry density of bottom ash is higher than 1.5 g/cm³, whereas its specific density varies from 1.5 to 2.4 g/cm³. Depending on the waste input and combustion conditions, the composition of the fractions may also vary considerably (Table 1). Approximately 80–90 wt % of bottom ash consist of SiO₂, FeO, CaO, Al₂O₃, Na₂O, K₂O, and C in proportions similar to those found in basalts, whereas Mg, Ti, Cl, Mn, Ba, Zn, Cu, Pb, and Cr occur in the 1–10 g/kg range. Bottom ash also contains traces of Sn, Sb, V, Mo, As, Se, Sr, Ni, Co, Ce, Ag, Hg, B, Br, F, and I (Table 1). As for the water content (moisture), it varies from 15 to 25 % for wet quenching.

Regarding mineralogy, a variety of silicate and oxide compounds are found (Table 2) along with metals, which mostly remain in their native form, and hydrated phases forming in spite of the fast quench upon reaction with water. But the major phases are aluminosilicate glasses, representing 30–55 wt %. Parts of them represent residual fragments of the original waste (Figure 3). As expected from their source, these scrap glass particles are clear and transparent under the optical microscope, displaying light brown to yellow hues and dark or brownish striations [*schlieren*]. In contrast, the newly formed glass particles are commonly inhomogeneous and contain vesicles and crystalline inclusions. The color of the individual grains varies from transparent and dark to opaque (Figure 2b). Their light to dark brown sections mostly occur around partially melted metal fragments. They often contain various silicates

Figure 2 The heterogeneous nature of bottom ash. (a) As seen with the eye. (b) As seen at a low magnification in a thin section of porous MSWI particles: transparent (TG), opaque (OG), and scrap glass (SG) glass along with metal (M) and lithic (L) fragments.

and opaque phases with fewer vesicles than in transparent glasses. The terms *isotropic* and *opaque glassy* melt products are used for the transparent and dark particles, respectively [5].

The SiO₂ content of these vitrified particles is significantly lower than that of scrap glass (Table 3). The transparent glasses are characterized by higher concentrations of SiO₂ (55–70 wt %) and Na₂O (7–14 wt %) and low concentrations of FeO and Al₂O₃. In contrast, opaque glasses have high contents of CaO, FeO, and Al₂O₃ and low concentrations of SiO₂ (34–40 wt %) and Na₂O (3–5 wt %). Minor amounts of heavy metals are found only in opaque glasses.

Microscopic investigations show the growth of well-developed euhedral crystals or crystals with skeletal or hopper structures within the vitrified materials (Figures 4 and 5). These occur as isolated elongate laths or spherulites of acicular crystals [5, 7]. Isolated silicates

(melilite, pyroxene) or black octahedra or cubes of spinel phases can be observed within the dark schlieren (Figure 5). Isolated octahedra or cubic forms are typical of the oxide phases.

2.3 Fly Ash and APC Residues

The flue gas transports dust particles and volatile compounds from the feedstock. These condense upon rapid cooling into particles smaller than 2 mm, called fly ash, whose specific density ranges from 1 to 4 g/cm³. Before any further treatment of the gaseous effluent, this loose material with an overall density lower than 1 g/cm³ is removed at the end of the heat transformation stage by processes such as electrostatic precipitation (Figure 1). Its nature and composition depend on various processes such as vaporization, melting, crystallization, and precipitation during incineration and subsequent treatment of the flue gas [4, 8]. A majority of these particles are chlorides and sulfates, which may deposit on the surface of the heat exchanger (hence their name *boiler ash*) and cause severe corrosion. Fly ash shows significant chemical and mineralogical heterogeneities even within individual particles. They are composed of volatile elements, notably K, Cl, Zn, and S, which are present as extremely fine-grained mixtures of chloride and sulfate minerals.

The rest of the particles represents up to 40 wt % of fly ash. They mainly consist of glass spheres 20–50 µm in

diameter with a relatively smooth surface (Figure 6), which are either hollow or filled, some of them bearing on their surface particles with a size of hundreds of nanometers. They are mainly composed of calcium aluminosilicates (Table 4, spots 6 and 7). In addition, crystalline oxides (quartz and metal oxides), silicates (melilite),

alloys, and metal (Si) compounds are present. As for heavy metals, they can occur as oxides like Pb_3O_4 and PbO but are in most cases bound in the glass (spots 2–5 in Table 4) and magnetic phases.

After fly-ash condensation, the flue gas still carries many impurities that must be removed to meet the emissions limits for specific pollutants before being released into the atmosphere. The composition of the resulting APC residues then depends on the cleaning procedure adopted, e.g. dry adsorption, quasi-dry process, or wet scrubbing. The amount of APC residues usually ranges from 2 to 5 wt % of the original waste [8]. The amount of heavy metals in the salt-rich fraction is high. Because of contamination with dioxin and furan, this fraction is classified as hazardous waste. This ash is highly soluble as about 25–85 wt % of the material can dissolve in water. According to their distribution coefficients, the highly volatile species accumulate in the fly ash and/or APC residues, leading to the higher concentration of Pb, Zn, Hg, Cd, and As in fly ash.

2.4 Dry Discharge of Bottom Ash

A new dry-discharge technology has been recently introduced. An additional (tertiary) air inlet is installed at the end of the combustion chamber. On one side, it cools down the bottom ash. On the other, it supports the after-burning of organic particles during the incineration process and leads to a reduction of the TOC content by more than 50%. As a result, the loss of ignition (LOI) is insignificant for dry compared with wet-discharged ash, and the separation of the particles is much easier because agglomeration of the finest particles is avoided. It follows that the recovery of metals, both ferrous and nonferrous, and also mineral particles is more efficient. Further benefit of this procedure is a drastic decrease of the leachability of heavy metals. During the procedure, very fine particles are generated, so this dust emission needs special treatment. One concept is to separate the dust in situ and recirculate it to the combustion chamber together with the tertiary air inlet.

2.5 Advanced Thermal Treatment by Pyrolysis and Gasification

In Western countries, waste is mostly burned between 800 and 1000 °C. Few attempts have been made at vitrifying the residues. In Eastern countries (e.g. Japan, Taiwan, or China), in contrast, vitrification of MSW and of fly ash sewage ashes is more usual. Particularly in Japan, a long debate in the 1990s about dioxins in residues initiated a new incineration technology aiming for

decomposing dioxin components and reusing the molten residues. In this case the content of vitrified material can range between 60 and 85 % of the total volume of the particles.

In one concept, solid waste is melted between 1300 and 1700 °C by a plasma arc, an electric resistance, a coke bed, or a fluidized bed heated by waste combustion. Another concept is waste pyrolysis, which is based on the thermal degradation of a substance in the absence of oxygen at rather low temperatures of 300–850 °C. The result is a mixture of gases termed *syngas* with a high calorific value ranging from 10 to 20 MJ/m³ (referred to room pressure and temperature). In general, metals and inert materials (such as rubble) are separated before the glass waste is processed.

Yet another concept is a two-step gasification system [9, 10]. Metals, glass, and other materials that cannot be gasified are separated from the waste stream before the onset of the gasification process. The first step is a combination of pyrolysis and combustion with partial oxidation of the waste above 650 °C. It includes the conversion of waste into a secondary energy carrier. In the second step, the residues are vitrified above 1300 °C to ensure a decrease of the PCDD/PCDF concentrations. Here, an option is to separate the heavy metals with the lowest boiling points during the first step and recover them as metals.

In contrast, the highly volatile compounds accumulate in the fly ash, where more than 90 % of Cl, 95 % of Pb, and 92 % of Zn are found.

Vitrification of waste by the Siemens Thermal Waste Recycling Technology [7] is a concept comparable with a gasification–vitrification procedure. The waste is first pre-degraded thermally at 450 °C. After removal of metals and inert particles, the remaining material, mainly consisting of C, SiO_2 , CaO, MgO, and Fe_2O_3 , is burned at 1300 °C. About 95–99 % of the particles formed are glassy, whereas only 1–5 % consist of crystalline phases like melilite, pyroxene, and spinel. These glass particles are more homogeneous than observed for the vitrified compounds obtained by conventional combustion. As indicated by the results of three different campaigns (Table 4), remarkably low contents of SiO_2 and high concentrations Al_2O_3 are observed, which are similar to those of opaque glasses [7]. The amounts of P_2O_5 , SO_3 , and heavy metals in these glasses are high. In general these metals are incorporated in the spinel phase. A detailed study of the relationships between the chemistry of bottom ash and the observed mineral phases has shown that high alkali and low silica concentrations favor the formation of melilite, whereas lower alkali contents and high silica contents promote the crystallization of plagioclase feldspars and/or pyroxenes [5, 7].

3 Environmental Impact of MSWI Residues

3.1 Leachability

Weathering is a spontaneous process whereby a material reacts to adapt to changes in parameters of its environment such as pH, redox potential, temperature, and humidity conditions as well as to the concentration of reacting agents (e.g. CO_2). Several interrelated processes may occur, including hydrolysis, pozzolanic solidification, dissolution/precipitation, carbonation, oxidation/reduction, surface complexation, sorption, ion exchange, and formation of solid solutions as well as mineral neoformation [8]. The alteration of MSWI residue leads to the mobilization of various species. The stability of crystalline and glass phases determines the leachability of heavy metals in bottom and fly ashes. Continuous mineralogical changes over time and the formation of new phases control the leachability of the residues. Therefore, the release of soluble species, namely, heavy metals and salts, may vary significantly with time.

Alteration of MSWI residues causes significant change in mineralogy. Newly formed minerals are anhydrite and gypsum [$\text{CaSO}_4(\text{H}_2\text{O})_2$], ettringite, hydrocalumite [$\text{Ca}_2\text{Al}(\text{OH})_6\text{Cl}\cdot 2\text{H}_2\text{O}$], (Fe-containing) Ca-(silicate) hydrates (e.g. C-S-H, C-A-H), gibbsite [$\text{Al}(\text{OH})_3$], rosenhahnite [$\text{Ca}_3\text{Si}_3\text{O}_8(\text{OH})_{1.9}(\text{CO}_3)_{0.1}$], zeolite, hematite, ferrous iron oxide, kaolinite, calcite, and amorphous phases [11–13]. As already stated, toxic ingredients are typically present as salts in fly ash. Chlorides such as halite [NaCl] and sylvite [KCl] are commonly identified. They control the leaching of Cl, K, and Na, whereas leaching of Zn may be due to the dissolution of K_2ZnCl_4 and ZnCl_2 . Heavy metal salts and hydroxides are often observed, e.g. CuCl_2 , $2\text{CuCl}_2\cdot\text{H}_2\text{O}$, ZnSO_4 , amorphous ZnO , calcium hydroxozincate [$\text{Ca}[\text{Zn}(\text{OH})_3]_2\cdot 2\text{H}_2\text{O}$], malachite [$\text{CuCO}_3\cdot\text{Cu}(\text{OH})_2$], azurite [$2\text{CuCO}_3\cdot\text{Cu}(\text{OH})_2$], yellow-brown lepidocrocite [$\gamma\text{-FeOOH}$], and goethite [$\alpha\text{-FeOOH}$] or FeCl_2 , FeCl_3 [11, 13].

3.2 Alteration of Glass Particles

Because studies of MSWI bottom ash have focused on long-term leaching, only a few of them have described the alteration of the glass phases. With aging, it appears that the glass fraction decreases from a maximum of 45 wt % to around 30 wt % [12]. Leaching first causes the formation of a gel layer because of the reactivity of the vitrified particles. Depending on glass composition, different reactions may occur in an open environment with high rates of water infiltration: (i) in situ transformation on the surface of the silica-rich glass and (ii) formation

of a leaching layer by preferential dissolution of the network modifiers of aluminosilicate glasses and formation of an amorphous or partly crystalline phase on the surface [14]. After one week of leaching, the first effects observed at the glass surface are precipitation of calcium silicate hydrates such as ettringite, tobermorite [$\text{Ca}_5\text{Si}_6\text{O}_{16}(\text{OH})_2\cdot 4\text{H}_2\text{O}$], zeolites (likely Ca chabazite [$(\text{Ca},\text{K}_2,\text{Na}_2)_2[\text{Al}_2\text{Si}_4\text{O}_{12}]_2\cdot 12\text{H}_2\text{O}$]), natrolite [$\text{Na}_2(\text{Al}_2\text{Si}_3\text{O}_{10})\cdot 2\text{H}_2\text{O}$]), and hydroxyapatite [$\text{Ca}_5(\text{OH})(\text{PO}_4)_3$] [11]. This assemblage results from a pH higher than 10 and high concentrations of chloride and sulfate in the solution. The kinetics of course largely depends on the environmental and boundary conditions. At acid or alkaline pH, the alteration of glass is much faster than at intermediate values. In a study of long-term natural weathering of glasses in MSWI bottom ash, the formation of a well-ordered illite clay was observed after 12 years [14]. In general, the weathering of glass phases in bottom ash is faster than that of natural glass [14, 15].

The transformation of glass is sensitive to environmental factors such as temperature and moisture. Changes in these parameters may cause shrinkage or expansion of the gels [15], whereas alkalinity regulates the Si/Al ratio of the solution and, thus, the Si/Al ratio of the amorphous hydrous aluminosilicate phase as an intermediate reaction product [14]. Besides, the mechanical liberation and/or dissolution of the embedded metal inclusions has an impact on the alteration of the glass whose dissolution may lead to the dispersion of the heavy metals within an unknown time frame [13].

The long-term alteration of glass obtained by an advanced thermal treatment termed *Schwel-Brenn-Verfahren* has been studied for a glass first homogenized at 1500°C and then tempered at $700\text{--}750^\circ\text{C}$ [7]. Dynamic leaching performed with distilled H_2O at 100°C in a Soxhlet extractor retarded the development of saturation effects on the surface of the glasses. After a reaction time of 1000 hours, the surface was completely covered by a brownish layer depleted in Si and Al and enriched in Fe, Cr, Cu, Mn, and Zn. The formation of goethite and hydroxyapatite was attributed to congruent dissolution of the glass. The corrosion rate of this glass is high, being four times faster than for volcanic glasses under the same conditions.

In a second dynamic test, an accelerated leaching procedure was performed at 200°C and pH 12.5 [7]. After a 100-day reaction under $\text{Ca}(\text{OH})_2$ saturation conditions, the solution was cooled down to ambient temperature, and the precipitates were analyzed. The growth of tobermorite $11\text{ \AA}$ and natrolite on the glass surface was observed. The presence of these minerals matches with the results of weathering studies of bottom ash [11, 14]. Glass leaching at room temperature and pH 11 caused an

increase in Zn and Cu concentrations in the solution up to 20 mg/L. This result indicates an enhanced release of heavy metals with time. The occurrence of etch pits on the surface was accompanied by a depletion of alkali and earth alkali elements. Furthermore, quartz and clay minerals of the montmorillonite group covered the surface.

The stability of the vitrified particles is a key factor in the long-term evolution of bottom ash. It can be roughly estimated from the calculated bulk polymerization of the glass as given by the ratio of nonbridging oxygens to tetrahedral cations (Chapter 2.4). Whereas this NOB/T ratio varies from 0.3 to 0.7 for opaque glasses, it is about 0.5 for transparent glasses (Table 4). Such rather low values translate into relatively ready corrosion. Vitrification of the residues at higher temperatures thus ensures a better glass stability as it causes the NOB/T ratio to increase to values in the range of 0.66–0.97 (Table 4).

3.3 MSWI Ashes as Aggregate Materials

Because untreated MSW residues are waste materials usually disposed of in landfill sites, efforts have been made to transform them instead into useful materials. Limitations in this respect result from the leachability of toxic heavy metals such as Pb, Cd, As, Sb, Hg, Sn, Cr, Zn, and Cu and from the high amounts of chlorides and sulfates concentrating in bottom and fly ashes and in APC residues. This is why both residues are classified as hazardous waste and require special control. Hence, the issue at stake here is the immobilization of toxic components and, in addition, the destruction of dioxins in fly ash.

Washing of MSW residues reduces the concentration of these elements, in particular of chlorine, to acceptable levels [8, 10]. The extraction of heavy metals depends on pH and liquid to solid (L/S) ratio as well as on the extracting agent [8]. Bottom ash treated in this way can be utilized as road base material, in cement and concrete production, as interim landfill cover, or as backfill material. Fly ash is often applied in cement and concrete production. In some cases, the harmful elements in the MSW residues are immobilized in the matrix [8], e.g. by solidification with cement, or stabilized with substances such as phosphates, ferrous sulfates, colloidal aluminate oxide, sodium sulfide, or calcium aluminate.

In view of the long-term reactivity of fly ash, vitrification has been considered as an interesting alternative to immobilize their toxic components. Numerous studies have aimed at producing a glass or glass ceramics either directly from the solid waste or by addition of various components. The main option is to obtain durable materials with a minimum of glass-forming or glass-modifying additives. These materials should consist of a glassy matrix with 50 up to 95 vol % crystalline materials. An

overview of the different studies has been given [10], whose main features are summarized below.

A comparison of conventional and advanced thermal treatment systems confirms that the fraction of vitrified particles increases with the combustion temperature and combustion time, so it is possible to vitrify bottom ash without additives above 1400 °C. At higher temperatures a metallic melt mainly composed of a Fe–Cu alloy and P, C, S, Si, Ni, Cr, W, Sn, Sb, and Na impurities can be separated from a silicate melt with small quantities of S, P, Cu, Zn, Ba, Pb, Cr, and Mn [10].

Vitrification of fly ash at 1350 °C causes increases in the contents of SiO₂ (19.8 → 43.2 wt %), MgO (3.8 → 7.5), and Al₂O₃ (7.0 → 15.5) and significant decreases in those of Na₂O (6.7 → 0.2) and K₂O (6.2 → 0.7) as a result of alkali volatilization [16]. This procedure generates secondary ash, however, which comprises 10 and 60 wt % of heavy metal and alkali chlorides, respectively [10]. This secondary ash is returned to the vitrification furnace. Less than 1 wt % chlorine then remains in the glass so the leachability of toxic species is markedly reduced. Washing the fly ash to remove chlorine and imposing a high partial pressure of oxygen promote the retention of heavy metals in the solids during vitrification [10].

Hydrothermal treatments of fly ash modify the mineralogical compositions and, thus, the relative proportion of aluminosilicate glasses and crystalline phases like tobermorite, a hydrogarnet mineral close to katoite, and zeolitic compounds. These glasses are the most abundant and most unstable phases during the hydrothermal treatment [17].

To optimize the relative ratios of Al₂O₃, SiO₂, and Na₂O for melting bottom and fly ash, additives have also been tested in the form of glass cullet, feldspar, or clay by-products. In general, additives improve the mechanical properties of the mineral phases crystallizing from the melt, which are diopside [CaMgSi₂O₆], wollastonite, and anorthite [CaAl₂Si₂O₈]. The optimal results for chemical durability have been obtained with the addition to bottom ash of 4 wt % fly ash and 43 wt % feldspar. Because it has also been recognized that chlorides have a negative effect on vitrification, either fly ash should be washed to remove the soluble salts or MgO or SiO₂ be added for melting at the higher temperature of 1500 °C.

Many studies have dealt with the production of glass ceramics from vitrified ash. In these cases the duration and temperature of the heat treatments are of course the fundamental parameters. The sintering process is affected by addition of clay or alumina waste [10]. Building materials with pink, black, reddish brown, and blue colors have even been produced from bottom-ash-based glass ceramics with various additives like TiO₂, MnO₂, Fe₂O₃, or glaze of cobalt aluminum oxide [18].

As expected, tests indicate that these glass ceramics possess better mechanical and thermal properties than their parent glasses (Chapter 7.11). Applications for ash vitrified at temperatures above 750 °C include road base material, blasting grit, embankments, and production of construction and decorative materials like ceramic tiles, pavement bricks, and water-permeable blocks [19]. A special case involves the *thermite* pyrotechnic process whereby melting is achieved by a strongly exothermic redox reaction caused by the reduction of a metallic or a nonmetallic oxide (e.g. FeO) by a metal (e.g. Al). Mixtures containing up to 30 wt % fly ash have been successfully melted in this way at temperatures from 1350 to 2200 °C [16] to yield more than 91 wt % of iron as an alloy and the other nonreactive oxides as slag. The latter incorporates the heavy metals in the glassy matrix. With increasing temperatures, Cd increasingly partitions into the flue gas, whereas Pb, Zn, and Cu preferentially remain in the vitrified particles.

4 Special Residues

4.1 Residues of Coal (Co-)combustion

About 40% of the world's electricity needs are provided by combustion of coal at temperatures higher than 1200 °C in power plants. The calorific value of the coal determines the ash content, which is typically about 10 wt % but can be as high as 40 % for the lowest grades [20]. As one of the largest types of industrial waste, these coal combustion residues (CCR) also include fly ash (60 %), bottom ash (15 %), and boiler ash (<2 %) along with flue-gas desulfurization (FGD) materials (25 %), which may be used to produce gypsum. About 780 million tons of CCR have been produced worldwide in 2010 and 130 in 2014 in the United States alone.

In general, fly-ash particles have a spherical shape whose size ranges between 0.5 and 300 µm. They mainly consist of amorphous, quenched glass composed of SiO₂, Al₂O₃, Fe₂O₃, and minor amounts of CaO. The mineralogy includes quartz (or partly cristobalite), mullite [SiO₂·2Al₂O₃], and the iron oxides hematite, magnetite, and/or maghemite [γ -Fe₂O₃]. Anhydrite, free lime, portlandite, calcite, periclase [MgO], sylvite, halite, rutile, and anatase [TiO₂] may also occur. In Ca-rich fly ash, the main phases identified are anorthite, gehlenite [CaAl₂Si₂O₇], and åkermanite [Ca₂MgSi₂O₇] (the main end members of the melilite group) and various calcium silicates and calcium aluminates.

Depending upon the specific coal-bed properties, CCR may include one or more of the following partly hazardous species, mostly in trace concentrations: B, Cd, Cr (as Cr⁺⁶), Co, Pb, Hg, Mn, Mo, Se, Sr, Th, and V, light

metals (Be), or metalloids (As, Sb). Coal in addition contains naturally occurring radioactive materials (NORM), including U, Th, Ra, and Rn. These elements are preferentially concentrated by a factor of 10 or more in the fly ash where their concentration can, for instance, reach about 150–180 ppm for uranium. Although the radioactivity released can then be higher than around a nuclear power plant, the levels remain well below the safety limits.

Upon combustion very small concentrations of organics like dioxins and polycyclic aromatic hydrocarbon (PAH) compounds could be available. It is these organic compounds that make the utilization of fly ash problematic. Depending on coal composition, two types of fly ash classes are defined by ASTM C618 (American Section of the International Association for Testing Materials): (i) obtained from anthracite and bituminous coal, class F ashes possess pozzolanic properties but need a cementing agent as a result of their lime content lower than 7%; and (ii) as residues of lignite or subbituminous coal combustion, class C ashes contain more than 20% CaO and higher amounts of alkali and sulfates.

Usually these residues are landfilled either directly or after binding with concrete. In the United States, about half of them are recycled as a partial substitute for Portland cement in concrete production. These pozzolanic qualities are in addition put to use to encapsulate these residues in wallboard, roofing materials, and bricks. Attempts have also been made at using them in road base construction, soil amendment, land reclamation, and zeolite synthesis, as filler in polymers, and even as fertilizers in agriculture [10].

Vitrification of CCR has also been investigated, for instance, for obtaining a starting material replacing kaolinite in the production of cordierite ceramics. For vitrification of coal fly ash, temperatures higher than 1400 °C are necessary. Addition of MgO and TiO₂ decreases the viscosity of the melt. A DSC analysis showed that the nucleation rate reaches its maximum at 620 °C with Li₂O [10]. Depending on the ash composition, however, additives are indeed needed to obtain stable glasses (with more SiO₂) or glass ceramics (with less SiO₂). In one study, two different types of glasses were, for instance, obtained when ashes were mixed with glass cullet or dolomite and vitrified at a maximum temperature of 1500 °C. Glass conversion began at 600 °C for Na₂O–CaO–Al₂O₃–SiO₂ and at 670 °C for CaO–MgO–Fe₂O₃–Al₂O₃–SiO₂. Crystallization of pyroxene and wolastonite, and hence formation of glass ceramics, was achieved in the 900–1100 °C range. Either dense materials without open porosity or solid foams were obtained. One can also form samples by cold pressing followed by sintering in the 1125–1200 °C range. The materials exhibit high durability and low leachability. Likewise, glasses with an excellent durability can be obtained from fly ash.

4.2 Sewage and Dredging Sludges

Sewage sludges have high water contents of 50–70 %, so they are usually dewatered and/or partially dried. On a dry basis, their carbon content is about 30 wt %, and they bear a similar fraction of inorganic matter, which mainly consists of SiO_2 , Al_2O_3 , CaO , and P_2O_5 , together with small amounts of Fe_2O_3 , MgO , K_2O , and sulfate and trace amounts of the heavy metals Pb, Cd, Ba, Cu, Cr, Zn, and V [10]. This sludge is often landfilled or even dumped in the sea. Thanks to its high phosphorus content, it has alternatively been utilized as fertilizer on farmland. The occurrence of pathogens, micropollutants including sterols and hormones, and potentially toxic elements like Cd, Cu, Pb, Hg, Mo, Ni, Se, and Zn have raised in many countries concerns over agricultural uses of this waste. Incineration offers an alternative [10]. Combustion can be performed in fluidized-bed furnaces between 850 and 900 °C, but the fly ashes produced have then to be disposed of. Attempts have also been made at producing glasses and glass ceramics (see [10] for a review) with, for example, addition of fly ash, limestone, galvanic waste, or fluorite for vitrification between 1200 and 1450 °C. After sintering of the glass powder at 725 °C, glass ceramics with diopside and/or anorthite, depending on the bulk composition of the glass, have been alternatively obtained.

Dredging sludge removed from harbor basins or waterways may also contain relatively high concentrations of heavy metals (Mn, Pb, Cd, Zn, Hg), of metalloids (As, Se), and of other pollutants (organic hydrocarbons, PAH). These sludges are often dumped in the sea or are landfilled. In this case, one favors either bioremediation by introducing microorganisms to break down contaminants or stabilization by adding cement or bentonite clay to make handling easier. Because Cd, Cu, and Cr are often adsorbed by oxidizable organic matter and sulfides, exposition of the sludge to air causes oxidation of the reduced species, whereas acidification of the sludge by bacterial activity promotes the mobilization of the toxic elements. In view of their own low calorific value, dredged sediments must be mixed with high-caloric materials to make incineration possible, whereas addition of other materials is needed to adjust their high SiO_2 , Al_2O_3 , and CaO contents and low Fe_2O_3 , MgO , Na_2O , and K_2O concentrations. As an example [10], glass may be produced after mixing with MSWI ash and melting from 1300 to 1500 °C. By addition of glass cullet, the temperature needed decreases to 1200–1350 °C. In another study pellets of glass powder sintered at 937 °C have yielded glass ceramics with pyroxenes (diopside, augite) and melilite (gehlenite, akermanite) as major crystalline phases.

4.3 Special and Hazardous Waste

For incineration of hazardous waste, legal regulations restrict the emissions of organics, hydrogen chloride [HCl], and particulate matter (PM), as well as those of volatile components. To convert ash and metal residues into a stable glass form, one typically uses controlled-air incinerators, liquid injectors, fluidized-bed incinerators, or rotary kilns. These technologies are expected to achieve complete combustion above 1100 °C with sufficient combustion times. The composition of the ash depends on the primary characteristics of the waste. They are typically composed of carbon, salts, and metals.

Waste from the zinc hydrometallurgical process and red-mud waste have in general high concentrations of Fe_2O_3 , ZnO , PbO , SiO_2 , and CaO with smaller amount of Cu, As, Ni, Na, K, Al, Ti, and S [10]. To be vitrified, they can be mixed either with primary materials like sand, feldspar, limestone, or dolomite or with other waste like glass cullet, electric-arc furnace dust, carbon, or fly ash and then heated at 1400–1450 °C or even at lower temperatures after pretreatment at 850 °C. The products obtained are glass–ceramic paving tiles, covering panels, or glass fibers for insulation [10]. A particular type of hazardous waste is red mud from processing and extraction (without additives) of beryllium metal from beryl ore containing 1 to 1.7 wt % BeO . The leachability of Be in the vitreous opaque products decreases when samples are prepared at high temperatures (650 µg/g at 850 °C and only 0.04 µg/g at 1600 °C) [10].

Blast-furnace slags and dust from electric-arc furnace may also contain significant concentrations of Zn, Pb, Cu, Cr, Ni, Cd, and Mn, in addition to As or Ba, and be enriched in phosphorus. With the processes developed in the 1960s by British Iron and Steel Research Association, and independently in former Soviet Union, both yield without additives glass ceramics (*slagceram* and *slagsital*) containing (pseudo)wollastonite and anorthite or diopside, which have been commercialized in the construction industry thanks to their excellent mechanical properties, chemical durability, and high resistance to abrasion. In addition, glass and glass ceramics with sometimes very good durability have been prepared from mixtures with quartz sand or powder, feldspar, or kaolinite, Ca and NaH carbonate, glass cullet, or borax [10].

Cement dust has also been declared hazardous because of its very fine grain size. Likewise, plaster-contaminated building materials are considered as problematic because of the sulfate leachability from gypsum. Vitrification of these dust mixtures together with 30 wt % sodium borate glass has been achieved at 1100–1200 °C [10].

In metal-finishing and plating industries, heavy metals like Cu, Cr, Ni, Zn, and Pb occur in the galvanic waste with average contents of 10 wt % but also higher values

up to 40 wt %. Depending on production line and treatment procedure, this waste also contains high concentrations of calcium hydroxide, sulfate, chloride, or phosphate but practically no silica. To make vitrification possible, more than 60 wt % of silica-rich materials have to be added, for instance, in the form of feldspars or waste material from various industrial branches [10]. In most cases, colored glasses or glass ceramics are obtained. Additionally the production of alkali-resistant glass fibers has been proposed [10].

In the leather industry the hazard is caused by high Cr concentrations. Upon incineration Cr^{6+} -rich ashes are obtained, which could be used to produce colored porcelain tiles. Remarkable is the utilization of waste with up to 30 % Cr for vitreous ceramic bodies. When mixed with soda-lime glass, TiO_2 , and MgO , and pressed in bars, they vitrify at temperatures lower than 1000 °C. The leachability of chromium decreases with increasing annealing temperature [10].

Wastes with asbestos are classified as particularly dangerous not at all because of heavy metals or other pollutants, but because of the effects on human lungs of fibrous minerals such as amosite $[(\text{Fe,Mg})_7\text{Si}_8\text{O}_{22}(\text{OH})_2]$ and crocidolite $[\text{Na}_2\text{Fe}_5\text{Si}_8\text{O}_{22}(\text{OH,F,Cl})_2]$. Although various concepts have been proposed to treat them chemically before disposal, the most common practice is to seal them in big bags for storage in controlled landfill sites, sometimes after immobilization in cement to prevent the fibers from being exposed. Attempts have nonetheless been made at decomposing asbestos by calcination and annealing at high temperature to get secondary ceramic raw material. These include thermochemical pyrolysis (conversion in absence of oxygen) or plasma-arc treatment. Microwave heating has also been used successfully to vitrify asbestos. Temperatures of 700 °C are necessary to convert cement-asbestos materials to destroy the asbestos minerals. A retreatment with sodium hydroxide makes it easier to handle it. A special procedure is GeoMelt®, which relies on Joule melting and is also used to treat radioactive waste. It is an in situ vitrification technique and similar to the melting procedure used to treat contaminated land [10].

Electronic waste (e-waste) or *waste electrical and electronic equipment* (WEEE) is becoming an increasingly important issue as a secondary resource material for heavy metals and rare earth elements. Along with refrigerators and other appliances, it includes computers, monitors, printers, scanners, data storage devices, servers, networking systems, copiers, fax machines, radios, TVs, cell phones and pagers, entertainment device electronics, etc. Pyrometallurgy and hydrometallurgy are used to recover valuable metals. As exemplified by cathode-ray tubes (CRT), e-waste contains special glasses with high

concentrations of Pb, Ba, or Sr [10]. Various types of glass–ceramic composites have been produced by sintering at 930 °C of CRT glass cullet mixed with other materials such as dolomite and single-crystal alumina platelets. Alternatively, CRT cullet has been either used as a flux to produce tiles or mixed as sludge with calcium fluoride and melted at 1200 °C to obtain glass ceramics. Disposal of different kinds of batteries (Zn–carbon, Ni–Cd, Ni–MH, Li, Ag) has also to be considered. After extraction of the heavy metals from the metallic fraction, slags have been produced by vitrification of alkaline batteries with dolomite, lime, and glass cullet at 1450 °C in graphite crucibles.

As for medical waste, this material is very inhomogeneous. It includes infectious and noninfectious material and possibly radioactive elements. It is partly treated by chemical disinfection or sterilization and afterward disposed in landfill sites, but most of it is incinerated, generally at temperatures higher than 1100 °C. The residues are comparable with MSWI bottom and fly ashes. Another method is plasma-torch melting, which is used to melt the waste at 1550 °C and yield a vitreous slag and a metallic fraction [10].

5 Perspectives

With socioeconomic development the volume of waste has increased tremendously over time, which has sustained a parallel growth of landfills all over the world. Leaving aside the much more important industrial or construction waste, 300–400 kg of domestic waste is, for instance, produced per person and per year in Europe. If 36 % of the waste is recycled, the rest is landfilled or burned. The introduction of incineration in the late nineteenth century has thus represented a convenient way to reduce drastically the volume of waste and, in addition, to immobilize contaminants and to eliminate many toxic agents and substances. These advantages have made incineration of municipal waste a standard method in most industrial countries, in particular when land space for disposal is scarce, which has proven to be a safe method to treat hazardous and clinical waste. Although air pollution caused by the emissions of heavy metals or organic pollutants is now technically and legally controlled, the occurrence of leachable toxic compounds in combustion residues and of tiny glass particles and other reactive components makes further progress in waste inertization desirable.

In this context, conversion of ash into stable, homogeneous silicate glasses should be especially interesting as the production of usable glass ceramics would allow that the

costs of the high-temperature processes could be partly offset. In practice, sinter-crystallization of combustion residues has the dual advantage of combining lower heating temperature with reduced volatilization losses. Although many processes are still at the laboratory stage, vitrification of fly ash or asbestos are already commercially used. In parallel, interest is being paid to using MSWI residues as sources of economically valuable materials. Dry discharge of bottom ash has, for example, been developed to optimize recycling of ash particles. Likewise, various concepts are tested to recover metals, taking, for instance, advantage of the fact [5] that heavy metals are preferentially incorporated in the opaque glasses of the MSWI residues, which form at combustions temperatures between 1000 and 1400 °C.

In all applications, however, risk assessment remains of great concern to government and society. In most countries the reuse of residues such as bottom ash is currently regulated on the basis of leaching tests whose results are in turn valuable to optimize the chemical compositions and fabrication processes of these materials. The use of various kinds of incineration ash for roads, pavements, embankments, or construction materials is now critically assessed to reduce the diffusion of toxic elements in the environment to harmless levels.

Nuclear Waste Vitrification

Olivier Pinet, Etienne Vernaz, Christian Ladirat, and Stéphane Gin

Commissariat à l'énergie atomique, DEN/DTCD Marcoule, Bagnols sur Cèze, France

1 Introduction

In its quest to deal with radioactive waste, the nuclear industry has found glass to be a durable material for stabilizing even the most radioactive waste in the solid state. This solution is now acknowledged to be the most suitable for immobilizing the radioactive products arising from the fission of uranium or plutonium in nuclear reactors. The disordered structure of glass makes it possible to incorporate the multiple species contained in high-level nuclear waste. Glass compositions formulated for this type of application must comply with complex specification requirements designed to reconcile several objectives: to maximize waste loading in the glass in order to minimize the final volume of the vitrified wasteform, to guarantee the quality of containment over the lifetime of the radionuclides it incorporates, and to fabricate them at an industrial scale in radioactive environments. The success with which researchers and engineers have met these challenges during the last decades has made it possible to pass to the stage of industrial operations in most countries exploiting nuclear energy. In addition, much work has also been made to address the legitimate issue of the long-term stability of vitrified waste under geological conditions. This chapter thus describes the historical milestones of nuclear waste vitrification, the key issues related to nuclear glass formulation, the knowledge acquired on the long-term stability of waste glasses, industrial vitrification plants operated for their fabrication, and finally the issue of long-term stability.

2 History of Nuclear Waste Vitrification

Fission product solutions began to accumulate after the Second World War in all countries where nuclear fuel was reprocessed for defense purposes (USA, USSR, UK, and France). Subsequently, high-level waste (HLW) solutions containing fission products were also produced through reprocessing of spent nuclear fuel. The countries that developed a nuclear industry and undertook reprocessing for commercial and military applications were the United States, Russia, the United Kingdom, France, China, and India. Germany and Belgium also began commercial reprocessing, but later stopped their programs. Japan is currently developing a complete fuel cycle including spent fuel reprocessing. An estimate of the waste quantities involved is presented in Table 1. A fraction of HLW generated by reprocessing of civilian spent fuel has been vitrified but the cumulative radioactivity immobilized in these HLW nuclear glasses, estimated at $35.4 \cdot 10^7$ TBq in 2012, is significantly higher than the estimated $7 \cdot 10^7$ TBq [1] of cumulative defense HLW. However, the volume of HLW nuclear glasses already produced is significantly lower than the HLW generated by defense programs that is mostly stored in liquid form.

In fuel cycles involving reprocessing, fission products account for only 5 wt % of the spent fuel but are the source of about 98% of the total radioactivity. Whereas energy production from the remaining 95% recoverable elements (uranium, plutonium, or even minor actinides) is a challenge for recycling spent fuel, reprocessing also recovers solutions containing fission products, which constitute the ultimate waste from nuclear power. These highly radioactive and very complex solutions containing some 40 chemical elements must be cooled and often continuously stirred to dissipate more efficiently their thermal power. Maintaining the waste in the liquid state

185 000	85 000	12 000 ^b 120 ^c	8·10 ⁵

^a Metric tons of heavy metal.

^b Assuming a typical value of 0.2 TWh of electricity per MTHM and a world electricity production of 2600 TWh for the year 2010.

^c Assuming a typical value of 0.1 m³ of glass per MTHM.

was not a sustainable option, however, so that research was undertaken to confine the activity in a solid material as inert as possible. The objective was to develop a compact material capable of incorporating the radionuclides from these solutions and of limiting the release of activity in contact with vectors capable of transporting them to the human environment, especially through the corrosive action of water.

Be they glassy, crystalline, or composite, many materials have been investigated since the 1950s. With the implementation of industrial applications, however, glass has emerged over the years as the benchmark solution for durable confinement of the waste arising from reprocessing spent nuclear fuel. Glass has the advantage of incorporating most of the oxides contained in fission product solutions. Glass in addition provides homogeneity and flexibility for use with a range of Fission product solutions and can be fabricated at an industrial scale in radioactive environments. Crystalline materials such as Synroc have also been considered because they exhibit an even better chemical durability than that of glass. But they often come up against limits for the incorporation of fission products, as in the case of feldspar or mica tested during the 1950s, and also raise difficulties related to radionuclide partitioning between different phases, resistance to amorphization of glass-forming phases under irradiation, and implementation at the industrial scale.

In the 1950s at Chalk River, Canada, a radioactive waste solution was immobilized by incorporation at 1350 °C in a nepheline syenite (an Al₂O₃- and alkali oxide-rich rock) to which lime (CaO) was added. In France, the first radioactive glass was synthesized in 1957 at a laboratory scale at the Fontenay-aux-Roses site, and then at a larger scale (10 kg) at Marcoule in the 1960s with a sol–gel process. Other processes were tested at the same time in the United States at Richland in the Waste Solidification Engineering Prototype (WSEP) and in the United Kingdom at Harwell with the Fixation IN Glass of Active Liquors (FINGAL) process. By 1969, the PIVER semi-industrial scale pilot at Marcoule was used to vitrify fission product solutions produced by reprocessing spent

gas-graphite reactor fuel (1969–1973) and subsequently fuel from the Phenix fast neutron reactor (1979–1980). This was a batch process in which all the operations were carried out in a single furnace. In these semi-industrial pilots, glass batches were directly melted in a metallic canister (FINGAL) or in a furnace and then poured in a canister (WSEP, PIVER).

In France, such an achievement opened the way for industrial development (Figure 1), which began with the Marcoule vitrification facility (AVM) commissioned in 1978. In the 1980s, Russia and India also built industrial vitrification facilities in relation with their nuclear program, and the PAMELA process supported the cleanup program in Belgium. In the early 1990s, France and the United Kingdom commissioned the industrial vitrification facilities R7 and T7 at La Hague (Normandy) and WVP at Sellafield (Cumbria), respectively. In the same decade, the United States initiated a defense waste vitrification program at the Savannah River site (South Carolina) and cleanup operations in the civilian reprocessing facility at the West Valley site (New York). In Japan, the Tokai vitrification facility marked the beginning of Japanese operating experience in 1995 which is now applied at the Rokkasho site (North of Honshū). In Germany, the WEK vitrification facility was operated for nine months in Badewurtemberg in 2009–2010 for high-level liquid-waste treatment in the Karlsruhe cleanup program. In France, the first cold crucible melter was implemented in 2010 in the R7 facility at La Hague for new high-level liquid-waste treatment. This melter enables vitrification to be extended to a wider composition range of liquid waste.

3 Nuclear Glasses

3.1 Selection Criteria for Glass Formulation

The specification for the chemical composition of a containment glass represents a trade-off between three main objectives: satisfactory long-term resistance, chemical

Figure 1 Operation of industrial vitrification plants around the world.

flexibility ensuring the incorporation of dozens of chemical elements in the glass structure at the atomic scale, and feasible implementation by an industrial process.

The nature and quantity of the waste must also be taken into account in this trade-off. Both the radiotoxicity of the containment glass and the thermal power emitted depend on the concentrations and half-lives of the radionuclides loaded in the glass. Radioactive wastes are classified into several categories, namely high-, intermediate-, and low-level waste [1]. HLW contains fission products and minor actinide elements arising from the burnup of uranium or plutonium fuel. It can be vitrified after separation from the spent fuel in a reprocessing plant and can thus immobilize more than 95% of the total radioactivity generated by nuclear power plants. Intermediate-level waste (ILW) arises from decontamination and cleanup operations, and contains long-lived radionuclides for which geological disposal is envisaged, as for HLW. It is less radioactive than HLW and emits less thermal power. Low-level waste (LLW) contains limited quantities of long-lived radionuclides and needs to be kept out of reach for a few hundred years.

It follows from these considerations that HLW must be confined in a matrix with greater long-term resistance than those intended for the other waste categories [2]. Glass was thus selected first as containment matrix for

HLW because of its ability to incorporate a wide range of elements in its structure. The three criteria pertaining to the long-term use of nuclear glasses concern their stability with respect to the radioactivity emitted by the waste they contain, to corrosion by groundwater in a geological repository, and to the temperature rises induced by the thermal power of the radioactive elements.

Another factor in the choice of a glass formulation is waste loading in the glass, i.e. the mass fraction of mineral species in the initial waste that is incorporated into the net mass of glass. It determines the required glass volume, which is often small in comparison with the initial waste volumes. Waste loading is often limited by the formation of secondary phases in the glass melt during synthesis or cooling. The glass compositions, waste loading, and synthesis temperatures are therefore modulated according to the solubility of the elements contained in these secondary phases. In this regard, depending on the waste composition, molybdenum, rare earth elements, aluminum, and transition metals such as chromium, iron, and nickel have been identified as primary species that limit HLW waste loading at around 20 wt % [3]. Loading limits associated with thermal power release must also be taken into account for the disposal of HLW (Table 2).

The selected commercial vitrification process itself also constrains glass formulation. It determines the conditions

Table 2 Thermal power of R7T7 glass from α , β , and γ emitters over time (W/L glass).

Years after vitrification	α	$\beta\gamma$
1	0.82	14.2
10	0.65	6.8
100	0.22	0.8
300	0.15	0.008
1000	0.05	0.0002

under which the initial waste is blended with additives, the possible temperature range of synthesis, the expected reaction rates, and their related uncertainties. These conditions also determine the viscosity of the melt at the process temperature, which ranges from a few tens to slightly more than 10 Pa.s. In addition to their composition, the physical nature of chemical additives is subject to optimization. Premade base glass is often used. It minimizes off-gas volumes and process time insofar as it is not too refractory. But glasses must also be formulated to prevent unwanted phenomena from taking place upon melting. An example is foaming caused by redox reactions in which elements such as cerium and iron may participate depending on their content and the oxidizing conditions of the melting process. One must also control the settling of non-solubilized particles by adjusting the melting temperature above the liquidus to prevent crystal formation or by limiting the addition of waste containing insoluble noble metals and other elements that could form alloys with them, such as tellurium. The glass formulation must also be compatible with the heating mode in terms of suitable electrical and thermal properties in the melt (Chapter 1.3). The waste activity level also influences the operating procedures. Minimizing the process maintenance requirements is particularly important for the vitrification of HLW; in some cases, this criterion may favor glass formulations synthesized at lower temperature to limit corrosion and volatility.

For radioactive waste immobilization, borosilicate systems have been selected as the reference matrix compositions for HLW in most countries because they represent the best compromise between these various constraints. With silicon and boron as the main network formers, together with alkali and alkaline earth network modifiers, they represent a good trade-off by ensuring the required chemical durability of the final glass and a process temperature of around 1100 °C. Aluminum is added to the HLW solutions to ensure their satisfactory calcination and also to ensure a good homogeneity of the glass.

Alkali phosphate glass was alternatively used in Russia before the turn of the century; over borosilicate glass, it

had the advantage of lower synthesis temperatures of about 1000 °C and could better solubilize sulfates, a point which, however, is still under discussion. But this type of glass is no longer used because of its low chemical durability and significant corrosiveness, and it has further lost its appeal because of a change in reprocessing methods that no longer produce high-level solutions rich in sulfates [4]. Lead iron phosphate and iron phosphate formulations were also proposed for this purpose, but did not result in industrial-scale processes. For lower activity waste, aluminosilicate glass formulations have also been used, notably for vitrification processes at very high temperatures (>1300 °C) designed to immobilize a range of lower-level radioactive wastes [5] or other toxic wastes [5].

3.2 Nuclear Containment Glass Properties

Reprocessing of current nuclear fuel typically yields about 40 kg of fission products and minor actinides per metric ton of reprocessed uranium. The fission product and minor actinide waste streams are supplied to the vitrification process as a nitric acid solution, and must be dried and calcined before being incorporated in an oxide matrix. Depending on the process, this transformation is performed either in a preliminary step before vitrification or directly on the surface of the molten glass. In either way the fission product solutions (Table 3) become complex oxide mixtures that contain no glass network formers in appreciable amounts. Hence, incorporation of these chemical species in an oxide glass requires addition of network-forming and network-modifying oxides.

Table 3 Composition of reference fission product solution vitrified in R7 and T7 facilities at La Hague (g/L).

Element	g/L	Element	g/L
Na	14.09	Cs	3.72
Al	3.52	Ba	2.21
P	0.51	La	1.7
Cr, Fe, Ni	11.22	Ce	3.3
Rb	0.5	Pr	1.56
Sr	1.18	Nd	5.63
Y	0.65	Pm	0.1
Zr	6.48	Sm	1.12
Mo	4.7	Eu	0.18
Tc	1.16	Gd	0.11
Ru, Rh, Pd	5.48	U	0.11
Ag, Cd, Sn, Sb, Se	0.38	Pu	0
Te	0.67	Am, Cm, Np	1.08

These glass-forming additives are generally supplied as raw materials, glass flakes, or glass beads mixed with waste either before vitrification or simultaneously with the waste into the melter to minimize the off-gas volume and process time. A high-level nuclear waste containment glass consists of about 70–80 wt % of inactive oxides, known as vitrification additives (mainly SiO_2 , B_2O_3 , Na_2O , and Al_2O_3 in the case of borosilicates). Vitrification at an industrial scale must allow for possible composition variations resulting from uncertainties in the processes and waste composition. Fission product containment formulations are oxidized glasses where $\text{Fe}^{2+}/\text{Fe}^{3+} \ll 1$. Various borosilicate glass formulations (Table 4) have been developed to accommodate the variety of elements present in high-level nuclear waste. Their variations reflect differences in the nature of the fuel and the reprocessing process implemented and also differences in the composition of the solutions of fission products derived from nuclear materials generated by older processes developed for defense programs.

Glass formulations that give rise to homogeneous microstructures are preferred for HLW containment glass to make their industrial production easier and modeling of their long-term stability more reliable. Industrial HLW glass generally contains crystalline phases with a volume fraction of a few % at most, which results from partial devitrification upon cooling at temperatures below 900 °C. The most common crystalline phases are spinels $[(\text{Ni},\text{Zn})(\text{Cr},\text{Fe})_2\text{O}_4]$, mixed cerium and zirconium oxides, powellite (CaMoO_4), and rare earth silicates such as $\text{Ca}_2\text{Nd}_8\text{Si}_6\text{O}_{26}$ [3, 6]. In addition to these crystals, Pd,

Rh, Te metal particles and RuO_2 precipitate because the platinum group metals present in fission product solutions are not soluble in the borosilicate melt (Figure 2).

In some instances, radioactive waste has nonetheless been immobilized at an industrial scale in glassy matrices with a more complex microstructure. This has been the case in France at La Hague for high-activity UMo glass containing up to 12 wt % molybdenum in a glass-ceramics fabricated by melting (Figure 3), and in Switzerland at Würenlingen for glass matrices designed to confine LLW residues that may include crystallized and metallic phases after heat treatment.

The main physical characteristics of R7T7 nuclear waste glasses produced at La Hague are indicated in Table 5.

4 Long-Term Stability of Nuclear Glass

4.1 Glass Waste Storage Context

Nuclear waste glass is an amorphous, dense, and generally homogeneous material containing tens of oxides. Upon cooling, its temperature reaches T_g a few hours after pouring in the canister. Then glass undergoes cracking, which significantly increases its reactive surface area. The canister storage is designed to maintain the glass temperature significantly below T_g in spite of the heat produced by radioactive disintegrations. The fate of the

existing and future glass canisters is intimately related to the disposal concept. The question of safe management of HLW has been debated for decades and has converged on deep geological disposal. Moreover, it is acknowledged worldwide that a multiple-barrier design is the safest way to ensure low corrosion rates of wasteforms and the slow migration of radionuclides through the geosphere in case of canister degradation. As a consequence, demonstration of safety directly relies on the ability to predict accurately the source term (i.e. the flux of radionuclides released from the glass over time) and the fate of radionuclides in the geosphere and potentially in the biosphere for periods of up to 10⁶ years.

From a scientific point of view, calculating possible release of radionuclides is difficult because glass is a thermodynamically metastable phase, which, upon alteration by groundwater, undergoes an irreversible kinetically limited transformation into more stable phases. A robust answer to the stability issue requires a deep understanding of the mechanisms of the glass/water interaction from which a mathematical model can be derived. Modeling is necessary as glass durability depends on many parameters (such as temperature, pH, glass composition, radioactivity, the renewal rate of the contacting fluid, etc.) on different time and distance scales [7].

4.2 Chemical Durability of Glass

Whatever the glass composition and the alteration conditions, several interrelated processes can take place at the glass surface during corrosion: water diffusion, ion exchange between hydrogenated species and alkalis

weakly bonded to glass formers (also called interdiffusion), hydrolysis of covalent and ionic-covalent Si–O–M bonds (M = Si, Al, Zr, Fe, Zn, etc.), condensation of more or less detached species from the glass surface, and precipitation of crystalline phases from amorphous phases and soluble species. Nuclear glasses are dense materials in which water diffuses slowly: the effective diffusion coefficient of water typically ranges between 10^{-17} and 10^{-23} m²/s⁻ depending on temperature (25–90 °C), pH (3–10), and glass composition. As a result, corrosion of such materials is generally seen as a surface reaction from macroscopic to microscopic scales.

Depending on glass composition as well as on chemical and physical conditions near the glass surface, these mechanisms can contribute to or control the apparent dissolution rate, which is generally measured by the release of mobile species into the bulk solution. If their solubility is high, the glass components – including the radionuclides – remain dissolved in the solution. If not, they either remain at the glass surface to form an amorphous, porous, hydrated material called the gel layer (cf. Chapter 5.12), or they precipitate into stable crystalline phases (generally located at the surface of the gel).

Under conditions representative of geological disposal environments, the aforementioned mechanisms can be linked to three main stages of corrosion [7]: (i) the initial rate, (ii) the residual rate, and, in some cases, (iii) the resumption of relatively rapid alteration (Figure 4). For several reasons the “interdiffusion” step and the “rate drop” shown in Figure 4 are not considered as formal kinetic stages. Interdiffusion takes place at each of these kinetic stages but acts alone only for a very short time.

The rate drop simply represents a transition between the initial and residual rates accompanied by the progressive saturation of the solution with respect to silica and by the formation of various surface layers that could impact continued corrosion. There is general agreement that the initial dissolution rate is controlled by the hydrolysis of Si–O–M bonds, whereas the debate remains open concerning the mechanisms limiting the residual rate [8]. The mechanisms considered are the slow transformation of amorphous phases into more stable products, changes in the local solution concentration (especially the concentration of silicon), water diffusion into the glass, or transport limitations in a passivating layer. As a matter of fact, several of these mechanisms seem to compete but there is no consensus on their relative importance or mutual relationships [9]. The potential for the resumption of relatively rapid alteration appears to depend on a combination of glass composition and environment, particularly at high temperatures and/or in very alkaline solutions. Zeolites are the main type of minerals responsible for this phenomenon by consuming Si and Al released by the glass, such phases precipitate at the expense of the passivating layer.

The design of multiple-barrier systems – i.e. the nature and amount of materials placed between the glass and the host rock – is expected to affect strongly both the mechanisms and rate of glass corrosion (the latter typically ranging from tens to several hundreds of μm/year at 90 °C, depending on glass composition). For example, a concrete overpack, as in the Belgian design, emphasizes the protection of the overpack material through the engineering of a high-pH environment. Once the overpack is

Figure 4 Summary of the distinct stages of nuclear glass corrosion and related potential rate-limiting mechanisms. The duration of each stage depends on the glass composition and leaching conditions (temperature, pH, solution composition, renewal rate, etc.).

breached, however, this environment could maintain the glass in stage (i) or (iii), thanks to the precipitation of calcium-silicate hydrates and zeolite, as long as the composition of the pore water contacting the glass is fixed by concrete. Conversely, an environment with a lower pH and a low groundwater renewal rate, as in the current French or Japanese design, would allow the glass to be altered in stage (ii), leading to much lower glass corrosion rates, although recent findings indicate that the presence of iron (from the overpack) in the vicinity of glass could sustain glass corrosion at higher rates for a longer time than previously expected. In the concepts relying on a durable glass, it becomes of primary importance to improve our knowledge of the mechanistic controls behind both stage (ii) and stage (iii) alteration. This suggests a focus on water transport and aqueous species reactivity in nanoporous materials (hydrated glass and gel), monitoring of slow kinetics, and a better understanding of the nucleation and growth of stable crystalline phases. A common fundamental understanding in these areas will lead to improved mechanistic models, which will eventually take into account the rate sensitivity to the glass composition and the environmental conditions.

The predictability of the models is evaluated through dedicated integrated tests performed in the laboratory or in underground research laboratories (Mol in Belgium, Mont Terri in Switzerland, Bure in France) and by analogy with natural and archeological glass specimens [10]. The latter materials provide a unique means to verify the rate-limiting mechanisms that control glass alteration over a geological timescale in natural environments. Numerous results supporting current models have been obtained in recent years through investigations of Roman glass blocks altered in seawater, slag buried in clay from an archeological ironmaking site, the so-called chondrite meteorites, basaltic glasses altered in various environments, etc. [9].

4.3 Effect of Self-Irradiation

Among the different sources of radiation within HLW glasses (Chapter 3.13), recoil nuclei from α emitters are the main cause of structural changes and variations of glass properties such as density, Young's modulus, microhardness, etc. The problem is to determine to what extent the confinement properties of the glass are affected over time by self-irradiation. This question has spurred experimental and theoretical work for at least the last two decades. Borosilicate glasses have been found very tolerant to the different sources of irradiation because self-healing processes allow fast reconstruction of local damage [11]. At high doses, typically around 10^{18} α decays/g, most of the glass properties reach a steady state. Moreover, the slight evolution of the macroscopic properties observed

up to the threshold indicated above (for R7T7-type glass, the 0.5% density decrease, the 20–30% decrease of Young's modulus by 20–30%, and the 50–100% increase of fracture toughness) have been explained in terms of structural changes, thanks to material characterization at an atomic scale and molecular dynamics simulations. A connection between these changes and the fictive temperature has been established from an analogy between the effects of both ballistic damages and the quenching rate on the glass structure. Concerning the production of He by α decay, it has been shown that the rate of helium loss by diffusion should be fast enough to avoid the formation of gas bubbles.

But these reassuring answers cannot be easily generalized to glass-ceramics as it is known that certain crystals swell much more than homogeneous borosilicate glass. This feature could lead to internal stress and the formation of cracks, thus increasing the reactive surface area.

Another issue is still under consideration. Does radiolysis affect glass durability, especially under the residual rate regime which is expected to be actually relevant in the geological repository? Although preliminary results do not show significant differences in residual rates between inactive samples and α - or β -doped glass samples, a better understanding of the potential effects of irradiation on alteration mechanisms under irradiation is required to confirm these results.

4.4 Thermal Stability

From a theoretical standpoint, glass is a metastable phase that could evolve toward a more organized state over long periods of times (Chapter 3.3) through crystal nucleation and growth or transport of reactive species within the glass itself. It is known that below T_g , transport is rate-limiting and glass crystallization is very slow, even if one considers the timescale of geological disposal of nuclear glasses. Experimentally, accelerated tests have been conducted to determine the type of crystals that could form in nuclear glasses and the maximum potential fraction of crystals. Cerium oxide, spinels like ZnCrO_4 , powellite, and Si-bearing apatite are major phases reported in the literature that have been observed during heat treatment of borosilicate glasses of nuclear interest. In the case of R7T7 type glass, the maximum crystal fraction should not exceed a few volume %. This suggests that even if crystals were forming, they should not affect the confinement properties.

4.5 Conclusion About the Long-Term Stability of Nuclear Glass

Thanks to multidisciplinary research performed in recent decades, remarkable progress has been made on the issue

of radionuclide waste storage, which allows us to draw the following conclusion: nuclear glass canisters, if placed in a suitably designed environment could last several million years and thereby significantly limit the release of radionuclides toward the geosphere. Because glass properties are very sensitive to many factors, however, inappropriate environmental parameters such as a high pH or a high groundwater flow rate could drastically reduce the glass life time. In scenarios under development in the world, great care is thus taken to select very confining host rocks and to design efficient engineered barrier system that would guarantee a very low release of radionuclides from the vitreous matrices.

5 Industrial Implementation of Nuclear Waste Vitrification

The fission product solutions are incorporated into vitrified waste packages by the following main operations: evaporation of water; thermal conversion of chemical elements to oxides; production of glass after addition of a glass additives to form a borosilicate by melting in a furnace between 1050 and 1300 °C; pouring into canisters; cooling to produce a solid glass; and sealing of the canister. The fission product feed solutions are highly radioactive so that the vitrification processes must be carried out in shielded cells. Electrically heated melters are used to comply with safety and remote maintenance requirements.

5.1 Industrial Processes

Vitrification processes based on two distinct technologies have been developed around the world. With the first, vitrification is carried out in two steps in separate devices, the first for evaporation and calcination, the second for glass preparation and melting. Fission product solutions, as well as reagents and solutions recycled from the off-gas treatment system, are fed to the calciner, a rotating tubular kiln heated by a resistance furnace (Figure 5). Calcining results in evaporation of the solutions and partial conversion of the nitrates to oxides. The calcine from the rotating kiln falls into the melter together with the glass frit necessary to form the containment glass. Then the glass can be produced either in a metal melting pot induction-heated at 4 kHz to a temperature of about 1100 °C, or in a cold crucible melter where the melt is heated by induction at 300 kHz to about 1250 °C. The chemical and thermal homogeneity of the product is achieved by means of mechanical stirring and bubble-stirring by gas injection. The glass is poured in batches into stainless steel canisters containing about 400 kg of glass. After lid welding and external decontamination, the canisters are transferred to an interim storage unit. These technologies have been chosen in order to separate the process functions, to implement simple, compact technologies in which all the components are interchangeable for ease of use in a high-activity environment, and to facilitate upgrades in industrial facilities.

With the second process, vitrification is continuously performed. The feed solution is introduced directly into

Figure 5 Two-step vitrification process of nuclear waste with either “cold” (left) or “hot” (right) crucible melters.

Figure 6 Sketch of an LFCM liquid-fed ceramic melter equipped with a bottom drain valve and an overflow pouring spout.

the melter where the water is evaporated and the elements are converted to oxides on the surface of the melt (Figure 6). A reducing agent is sometimes added to the feed solution to control the redox potential of the molten glass in the melter. Glass frit or glass-forming chemicals are supplied to the melter at the same time as the vitrification feed solution to form the glass network. Glass additives or chemicals are added either in solid form or as a slurry in suspension in the feed solution. The glass forms on the surface of the melt. The liquid-fed ceramic melter (LFCM) or Joule heated ceramic melter (JHCM) is lined with refractory material consisting of zirconia, alumina, and chromium oxide. The melt is heated to 1150–1200 °C by an electric current flowing between water-cooled metal electrodes embedded in the refractory furnace walls. The glass can be poured into canisters continuously by overflow through a siphon or in batches through a thermal valve at the bottom of the melter. After lid welding and external decontamination, the canisters are transferred to an interim storage unit. The melting furnaces are generally massive refractory assemblies that allow very stable operation over their lifetime of between 5 and 10 years. At the end of its service, life the melting furnace is difficult to replace so that it constitutes a very bulky secondary waste item.

5.2 Industrial Vitrification Facilities for High-Level Liquid Waste Around the World

The main features and operating data for the industrial-scale high-level liquid waste (HLLW) vitrification facilities in each country are summarized in Table 6.

5.2.1 France

Three industrial vitrification facilities implementing the two-step vitrification process (calcining and glass melting) have been built in France.

The Marcoule vitrification facility (AVM), operated in conjunction with the UP1 reprocessing plant at Marcoule, had a calciner with an effluent evaporation capacity of 40 L/h and an induction-heated melter containing 150 kg of molten glass and capable of producing 18 kg of glass per hour. This facility was operated from 1978 to 2012.

The other two facilities, R7 and T7, are located at La Hague. The former, associated with the UP2-800 reprocessing plant, was commissioned in 1989. The latter, associated with the UP3 reprocessing plant, was then commissioned in 1992. Both include three vitrification lines, originally with a calcining unit which is a 4-m length rotating kiln, with a capacity of 76 l/h improving to 90 l/h and an induction-heated melter. It is an ovoid melter

containing 300 kg of molten glass and producing 25 kg of glass per hour. In 2010, the melter in one of the three lines of R7 was dismantled and replaced by a cold crucible melter to vitrify “legacy” intermediate-level liquid waste. This melter contains 400 kg of molten glass and produces up to 40 kg of glass per hour.

5.2.2 United Kingdom

An industrial vitrification facility was built at Sellafield in the United Kingdom implementing the two-step (calcination and melting) vitrification process in an induction-heated melting pot. Associated with the MAGNOX and THORP reprocessing plants, the waste vitrification plant (WVP) was commissioned in 1990 and initially included two vitrification lines with the same characteristics as the French units at La Hague. A third line with similar performance began operation in 2004.

5.2.3 United States

Two industrial facilities have been built in the United States.

In the West Valley Demonstration Project (WVDP), a vitrification demonstrator was associated with a PUREX and THOREX reprocessing plant for commercial spent fuel operated from 1996 to 2002. The LFCM, with a surface area of about 2.2 m² heated by three electrodes (including one at the bottom of the furnace), had a capacity of 35 kg/h. The glass was poured off through an overflow spout. When the commercial reprocessing project was stopped, the vitrification facility was being operated for the treatment of liquid waste. WVDP is now being dismantled.

At the Savannah River Site, the vitrification unit of the Defense Waste Processing Facility (DWPF) was built to vitrify 130 000 m³ of sludge and effluents from the defense reprocessing plant. It began operating in 1996. It includes a LFCM with a surface area of 2.6 m², with a side-mounted siphon to fill the glass canisters and a drain valve at the bottom of the melter. The furnace weighs 65 tons and holds 6500 kg of glass. The first melter was operated industrially from 1996 to 2002. The second melter equipped with an argon bubble-stirring system

has been in operation since 2004 and will likely be replaced from 2014.

5.2.4 Russia

The vitrification facility associated with the RT1 plant in the P.A. Mayak complex at Chelyabinsk implements EP-500 side-pouring electrode melters with an evaporation capacity of about 500 l/h. The first melter was commissioned in 1987, and four melters have been operated successively since then.

5.2.5 Belgium

The PAMELA vitrification facility was operated from 1985 to 1991 at the Eurochemic reprocessing plant near Mol, Belgium. It was equipped with a LFCM having a surface area of 0.7 m², a flat bottom with a drain valve, and an overflow pouring spout actuated by an airlift. The furnace weighs 18 tons and holds 750 kg of glass. Two melters were used successively, and both failed due to the accumulation of noble metals and aluminum-rich phases at the bottom of the unit. They vitrified about 500 metric tons of glass in 2201 canisters containing a total activity of $0.5 \cdot 10^6$ TBq. PAMELA vitrification facility was stopped when vitrification of the liquid waste coming from Eurochemic reprocessing plant decommissioning was complete.

5.2.6 Germany

The VEK vitrification facility associated with the WAK pilot reprocessing plant at Karlsruhe was built to vitrify 60 m³ of legacy HLLW. It was equipped with a LFCM having a surface area of 0.44 m², containing 450 kg of molten glass, with several pairs of heating electrodes. In order to process effluents containing noble metals and prevent their accumulation, the bottom of the melter was inclined at about a 60° angle and the melt was poured through a metal tube at the bottom of the unit. VEK was operated for a single campaign from September 2009 to June 2010. It is now being dismantled.

5.2.7 Japan

The Tokai Vitrification Plant (TVF) associated with the Tokai Reprocessing Plant (TRP) has a 0.7 m² ceramic melter tapering downward at a 45° angle. The glass melt is poured from a metal tube at the bottom of the melter. The plant began operating in 1995. The first melter (TVF1) was operated in 1995–1996 and again in 2000–2002. The second melter (TVF2) was commissioned in 2004 and operated until 2007. A technological development program is now in progress to improve melter operation in the presence of noble metals.

5.2.8 India

Vitrification processes are implemented at India's two reprocessing sites, Trombay and Tarapur. At Tarapur, the Waste Immobilization Plant (WIP) has been in operation since 1985, initially with two vitrification units that used induction-heated metal melting pots operating in batch mode supplied directly with the feed solution and glass frit. These melters were dismantled and replaced by two new units comprising the Advanced Vitrification System (AVS) with two JHCMs of about 1 m². The first ceramic melter operated for six years, and the second was only recently commissioned. At Trombay, three vitrification units with induction-heated metal melting pots operating have been operated in batch mode, supplied directly with the feed solution and glass frit.

5.3 New Vitrification Projects

New HLW vitrification projects are currently in progress throughout the world.

- In Japan, the KA vitrification facility associated with the Rokkasho-Mura commercial fuel reprocessing plant is awaiting the startup of commercial operation. It comprises two 2.6 m² LFCMs with walls inclined 45° and hold about 4 tons of glass. The production capacity of each unit will be about 35 kg of glass per hour.
- In India, a vitrification facility implementing enhanced technologies is now in the process of final inspection and approval at Kalpakkam.
- In China, the China Vitrification Project is now in progress at Guangyuan, the facility has been designed with a LFCM having a glass production capacity of about 30 kg/h.
- In the United States, vitrification units are being built at Hanford for high- and low-level defense liquid waste. The HLLW vitrification facility will use a LFCM with a surface area of 3.75 m², and is expected to be commissioned around 2022.

Vitrification processes were originally developed to immobilize HLLW. Along with other processes, they are also used for intermediate- and low-level liquid effluents and sludges. In Russia, for example, SIA Radon has been operating a cold crucible melter since 1999 to vitrify intermediate- and low-level liquid waste, producing more than 30 metric tons of glass. A vitrification facility is now under construction at Hanford, in the United States. It will operate with two 10 m² ceramic melters heated by Joule effect electrodes with a unit production capacity of 10 tons/day. The two-step vitrification process is also implemented in a cold crucible melter in France at La Hague to vitrify ILW solutions arising from decommissioning operations.

Low- and intermediate-level combustible solid waste can be incinerated to destroy organic material, as the ashes are simultaneously vitrified in the melter. An example is the Ulchin vitrification facility in South Korea, commissioned in 2009 for the incineration and vitrification of waste from commercial nuclear power plants. The waste is incinerated on the surface of a molten glass bath in a cold crucible melter. The processing capacity of this unit is 20 kg/h.

In Switzerland, an incineration-melting-vitrification process has been operated since 2004 for Very low-level waste (VLLW) and LLW in a plasma arc centrifugal treatment (PACT) system using a rotating crucible with a 1200 kW transferred arc plasma torch. After burning the organics with the plasma torch, the ashes and metal waste remaining in the melter are melted and/or vitrified. The processing capacity of the facility can reach 200 metric tons of waste per year.

6 Perspectives

An international consensus is emerging about the long-term quality of the containment provided by immobilization of high-level nuclear waste in glass, with a preference for borosilicate glass formulations. The cost of spent fuel reprocessing including glass canisters production is estimated to be a few percent of the total production cost of electricity [12]. For economic or political reasons, however, reprocessing of spent nuclear fuel with vitrification of the HLW has not been adopted by all countries producing nuclear electricity. Future changes in the positions of these countries could contribute to increased production of nuclear containment glasses with improvements in the industrial performance of the processes, such as extended melter lifetimes and larger production capacities. In the coming decades, improved disposal concepts for vitrified waste packages can be expected together with their actual implementation after a preliminary experimental stage.

It is now envisaged to extend vitrification to a broader range of radioactive waste. Facilities have already been implemented to vitrify radioactive effluents arising from cleanup and remediation (France), to vitrify various low-level radioactive wastefroms including hospital waste or low-activity waste from nuclear power plants (Switzerland, Japan, South Korea). Vitrification projects based on plasma technology are being investigated around the world and could lead to industrial applications in the coming decades [13]. They concern the immobilization of a range of radioactive waste or sludge. In addition to treating radioactive waste, vitrification is also a possible option for the treatment of toxic waste such as asbestos or the fly ash from domestic waste incineration

(Chapter 9.10). A few commercial facilities of this type have emerged, but the advantages of these treatments have not yet offset their cost in the eyes of policy-makers, although their positions could change in the light of the increasing importance of environmental issues associated with waste management in general.

The International Commission on Glass (ICG)

John M. Parker

Department of Materials Science and Engineering, Sheffield University, Sheffield, UK

1 Introduction: Origins of ICG and Founding Members

The International Commission on Glass is a unique body where experts from academia and industry meet to understand and solve practical and fundamental issues in glass science and production. Its roots lie in conversations in the 1920s between international glass experts, particularly Prof. William E.S Turner (1891–1963) [1] and Prof. Georg. R. Gehlloff (1882–1931). Prof. Turner was Head of the Department of Glass Technology in Sheffield, UK, and a Founding Member in 1916 of the Society of Glass Technology (SGT). Prof. Gehlloff was a Member of the Board of Directors of OSRAM in Berlin and Head of the Glass Laboratory at Weiswasser. He also represented the newly formed (1922) Deutsche Glastechnische Gesellschaft (DGG) based in Frankfurt am Main. Their societies arranged a joint conference in Aachen, a model for later ICG meetings (1928). They created technical committees to define terms and facilitate precision in the technical literature, standardize the methodologies for measuring thermal expansion, and test both chemical durability and refractivities.

Similar discussions were happening elsewhere (Figure 1). The SGT met with the Glass Division of the American Ceramic Society in 1920 and a reciprocal visit followed in 1928. Meetings with France and Belgium representatives took place in 1923 and 1924, respectively. After Gehlloff's untimely death (1931), Dr. H. Maurach, DGG Managing Director, continued with Turner to pursue the dream of extending such collaboration to other national organizations. Their aspirations bore fruit in 1933 when a formal document defining both a structure and aims was approved by six countries during the first

ICG Congress on Glass in Venice. Signatories were J. Antonio De Artigas (Spain), J. C. Hostetter (USA), B. Long (France), H. Maurach (Germany), A. Mauri (Italy), and W. E. S. Turner (England). Prof. Turner was its first President and Dr. Maurach its first Honorary Secretary. While World War II halted progress for a decade, the organization survived and has continued to grow. Its current status and activities will be reviewed in this chapter.

Acronyms

AC	Advisory Committee
CTC	Coordinating Technical Committee
EFONGA	European Forum on New Glass Applications
ICG	International Commission on Glass
MB	Management Board
NPO	National Participating Organization
SC	Steering Committee (used in early years for subcommittee)
TC	Technical Committee

2 ICG as an Organization

2.1 The Constitution

A formal constitution codifying those early dreams was not created until 1950, after formal discussions recommenced in 1948. The stated aims were *to promote and stimulate understanding and cooperation between different countries for the exchange of information on the art, science, and technology of glass by (i) serving as an international center for information exchange, (ii) assisting*

Reviewers: K. Bange, MK Consulting GmbH, Jugenheim, Germany
F. Nicoletti, Stevanato Group, Piombino Dese (PD), Italy

Figure 1 The formal atmosphere of a meeting of glass scientist in 1928 in Aachen. Front row, from left to right: G. R. Gehlhoff, K. Quasebart, W. E. S. Turner, and M. Von Vopelius. H. Maurach standing up behind Turner and Von Vopelius.

everywhere in the development of an interest in glass, (iii) arranging for the holding periodically of International Congresses and Technical Sessions on Glass, and (iv) preparing and issuing reports and surveys having an international character. The task of achieving this was delegated to an Executive Committee.

Managing these goals proved less than straightforward and required significant determination. In 1958 the Executive Committee added a Committee A – later the Coordinating Technical Committee (CTC) – and a Committee B. More changes in 1962–1963 redefined the organization and its working methods, particularly the roles of the Council, with ultimate overall responsibility; the Executive Committee, responsible for technical and scientific matters; and the Bureau, concerned with day-to-day matters.

In 1968 Charleroi, Belgium became the official seat of ICG, under a law giving legal status to international organizations established there. Consequently until 2001 most Treasurers were Belgian. From 1974 the Executive Committee became the Steering Committee (SC), responsible for evaluating, assessing, and approving ICG's activities, and the category of "Associated Members" was introduced. Such constitutional changes required approval by the Belgian authorities, who imposed additional modifications in 1978 and 1999 concerning for

instance the distribution of funds in the event of ICG's dissolution.

In 2001 ICG's base moved to Spain, a change only finally ratified in Belgium in 2005. Funds were transferred to accounts in Spain and Prof. A. Duran became the new Treasurer.

In 2008 a new constitution was approved, embodying changes designed to improve efficiency. The Bureau became the Management Board (MB), and the CTC Chair became its fifth member. Additional ICG membership categories were created: "Associated Member Companies" and "Individual Members." New operating guidelines were written.

Now the Council, consisting of the representatives of the National Participating Organizations (NPOs) and of the Associated Organizations, elects the administration. At its pinnacle is the MB, responsible for the day-to-day running (President, Vice-President, Executive Secretary, Treasurer, and CTC Chair). They are assisted by the SC, i.e. the MB plus up to six members elected by Council including the immediate Past President. Typically they meet twice a year, occasionally three times. Finally the CTC, responsible for all ICG's technical and scientific activities, reports to the SC.

Recently an Advisory Committee (AC) with four representatives from different parts of the world has been formed to work on nontechnical topics of concern to the ICG such as to connect it with other relevant bodies within the glass community. The AC includes members drawn from the SC. Its role and responsibilities are currently under review.

2.2 Personnel

The constitution limits the tenure of officers. The Presidential term has been three years for all but the early years of ICG's history. The Vice-President normally becomes the President elect after two years and accedes as President one year later, ensuring continuity. This natural progression has been broken only rarely, first in the early days of ICG and again in 1995–1996 when F. Nicoletti served temporarily as Vice-President after G. Nightingale resigned prematurely. A significant recent change has been to make the Vice-Presidential selection procedures more transparent. Proposals are submitted by the NPOs and each candidate presents his/her case. The MB and SC vote anonymously, and their choice requires final approval by Council. All ICG presidents are listed in Table 1.

Three people at the end of their terms were elected by Council as Honorary Presidents (Table 2), and six more people active within ICG received Honorary Vice-President status (Table 3). The Executive Secretaries and Treasurers are appointed annually but with no time limit (Table 4).

2.3 Funding and Expenditure

The ICG has no permanent office or paid staff although some of the MB receive an honorarium in lieu of expenses. It relies on individuals to give freely of their time and effort. Consequently its running costs are modest. They are financed by subscriptions from NPOs set according to the annual glass output of the respective countries. Additional income arises from Associated Organizations and Member Companies, the sale of publications and analytical standards, and royalties.

Technical Committees can be supported, for instance, through travel expenses for committee members in particular need or funding for projects such as the publication of books and workshop organization.

A major boost in 2005 was the award of an EU grant worth 1.6 million Euros to support specific TC activity (the European Forum on New Glass Applications [EFONGA]). Outcomes include the ICG Roadmapping process, the Montpellier Summer School, and an enhanced TC structure.

2.4 Web Pages

The official ICG web site is at www.icglass.org. Initially hosted by the University of Sheffield, it was transferred in 2011 to a company offering more facilities. The layout was improved to standards then current, and a Content Managed System was installed, which allowed online updating by anyone with password access, with the intention of offering TCs a platform to advertise their results. A further update in 2015 offers the latest editing facilities including links to social media.

Much of the technical content mirrors that in the annual reports produced by the CTC. Approximately 20 news items are added a year, more than half from NPOs. The number of hits has risen steadily at a rate faster than the overall increase in Internet traffic to almost 0.2 million p.a. in 2015. Web statistics also provide valuable insights into the nature of this traffic, for instance, showing that interest from countries not in ICG is significant. Behind the system is a secure address book. The site also offers TCs file storage facilities with access granted solely to committee members.

2.5 The ICG Brand

The ICG's formal title, approved in 1994, is "The International Commission on Glass," subtitled "Society of Scientific and Technical Organisations." The word "Society" replaced "Union," used from 1967 to 1994.

In 1967 ICG adopted an Egyptian hieroglyph with the connotation of "brilliance" as its symbol in communications after it had been used first at the 1965 Congress

(Figure 2). A simpler version was designed in 1994. Over time unapproved modifications appeared, and so it was redesigned in 2010 by ABIVIDRO in a contemporary style with strict guidelines for its use (Figure 3). Blue is the official ICG color, chosen in 1999.

3 The ICG Committees

3.1 The Coordinating Technical Committee and Its Technical Committees

From its inception, the ICG appreciated the value of working on technical issues together, and still today it

depends on its Technical Committees (TCs). A program was first formulated and agreed in 1950. Seven areas were identified: definitions, furnace efficiency survey methodology, effects of iron, annealing, international specifications, chemical and physical testing, and publication lists. Not until 1957 was a working framework devised though, based on a Committee A, “Science and Technology,” and a Committee B, “Form, Design, and Decoration.”

Subsequently Committee B struggled to formulate a working plan. It had no natural constituency within the ICG and many with interests in art, archeology, and history belonged to other global organizations (e.g. the International Association of the History of Glass). Finally a TC on “Archaeometry of Glass” was created in 1984 to bring artists and historians into the ICG and was ably led by Dr. R. Brill for many years.

Meanwhile Committee A elected a chair, secretary, and four members. Five subcommittees (SC A1–A5) were tasked to work on Definitions and Terminology, Chemical Durability, Temperature-Viscosity relations, and Furnace Operation. Increasing activity required better communications: conferences, publications, and annual reports. The SC A6 on “Mechanical Properties” was formed in 1961, and five more SCs were created in 1964.

In 1971 a fundamental overhaul clarified operating procedures and introduced more effective progress evaluation. TC Chairs were allowed longer in office, 3 + 3 + 3 years, with the possibility of reelection after one year, to promote continuity. Committee A became the CTC in 1983.

The CTC supervises and coordinates the activities of the various TCs, which carry out applied scientific investigations. Operating procedures continue to be reviewed and revised. The CTC Chair is appointed for 3 + 2 + 2 years, its Vice Chair is appointed for 3 + 2 years, and

Table 5 CTC Chairs (Committee A before 1983).

1988–1996	P. Sewell	(GB)
1996–	J. M. Parker	(GB)

the Secretary is reappointed annually (see Table 5). Additionally five members are appointed for 3 + 2 years. Meetings are either technical or business. TC Chairs can attend both but are specifically invited to the annual CTC technical meeting.

Over 500 experts are TC members, selected roughly equally from universities, research institutions, and industry. Their access to resources is contributed freely in the pursuit of the objectives of the individual TCs. They gain from sharing knowledge and expertise. Formally, for an individual to join an ICG committee requires the approval of the NPO responsible for that individual's country of domicile and ICG Council. Committee chairs though often approach suitable individuals initially and vice versa.

Technical Committees undertake laboratory round robins, comparative studies, topical meetings, and compile information (e.g. publishing scientific and technical papers and reports and assisting in creating standards and books). They also disseminate knowledge on glass in advanced educational courses and workshops. TCs communicate regularly and meet at least once annually, often at ICG meetings.

From 2009 TCs have been organized into clusters (basics; characterization; applications; glass production; communication, education, and history), each supported by a CTC member. Cooperation across cluster boundaries is encouraged as appropriate. The CTC publishes an annual report and evaluates TC activity.

Over the years many TCs have blossomed, fulfilled their roles, and closed. Others have evolved as circumstances changed. Some are new or even reformed. These changes

are driven by new inventions, new legislation, and different ways of communicating in the glass community. A summary is given in Table 6. A full history is in [2].

3.2 Membership

ICG's members are primarily national societies representing glass technologists and scientists in their country. These NPOs each appoint two representatives onto its governing body, the ICG Council. Where no National Glass Society exists, an appropriate business, university, or research institute can be assigned the status of NPO. Applications in the first place are made to the Executive Secretary.

Membership is dynamic. The initial group of six NPOs in 1933 is now 33. The countries currently represented on ICG Council are listed in Table 7a and b (2015) together with the dates they first joined. A few countries are no longer represented (Australia, Egypt, Indonesia, Ireland, Philippines, Yugoslavia), some have been represented by different NPOs at different points in their history, some NPOs have adopted new titles, and international borders have not remained the same. More details are in [2].

Six bodies either with international glass interests or more focused local interests have been granted the role of Associated Organization. Constitutional changes in 2008 allowed national and multinational companies with a strong glass bias to become Associated Member Companies. This stimulates involvement in TCs and other activities. As of 2015 there are 16 such members.

Exceptionally, Individual Members can be appointed.

4 Public Activities

4.1 Congresses and Conferences

ICG Congresses and Conferences provide valuable opportunities for glass scientists and technologists to meet and share information (Table 8). The first were in Venice, Italy, and the United Kingdom (London/Sheffield). Dr. Maurach had hoped to organize a third in Berlin in 1939 but WWII intervened. The next was not until 1953. Since then they have been triennial.

An appendix to the constitution gives rules for running International Congresses on Glass. While the primary organizers are the NPOs in the destination country, key ICG officers join an International Advisory Committee and a Scientific Committee, providing support and ensuring continuity. The Congress host is approved six years in advance by the ICG Council, following an invitation to all NPOs to bid.

Table 6 Technical Committees: title (years of operation).

TC01	Terminology (1958–1982) Publication and Terminology (1983–1994) Information and Communication (1996 to present)

TC21	Modelling of Glass Melts (1990–2000) Modelling of Glass Melting Processes (2000–2013) Glass Furnace Design and Operation (2013 to present)
TC22	Electrochemical Behaviour of Glass Melts (1992–2006) Structure–property relations (2009–2013)
TC23	Education and Training in Glass Science and Engineering (1992 to present)
TC24	Coatings on Glass (1995 to present)
TC25	Modelling of Glass Forming Processes (2000–2017)
TC26	Biosolubility of Glass (2000–2005) Structure and Vibrations (2009 to present)
TC27	Atomistic Simulation (2009 to present)
TC28	Glass Fibres for Reinforcement and Insulation (2017 to present)

Early congresses were multilingual with simultaneous translation. Now they are in English. Most offer publication. In 1998 for the first time papers were published on CD ROM. A more complete version of the table below gives Conference Presidents, Conference Organizers, and references to the published proceedings [2]. Two important papers have analyzed the evolution of the Congresses and submission trends such as the proportions of papers from industry vs. academia [2, 3].

ICG Congresses have grown significantly to between 700 and 1000 attendees who deliver up to 900 papers and posters. Their special features include:

- 1) Invited lectures reviewing progress in traditional areas and in new subjects such as optics, photonics, electronics, nanotechnology, coating technology, and biotechnology.
- 2) Sessions organized by TCs on their work.

When there is no Congress, Annual Conferences are held. These attract 200–400 participants and are an important part of the ICG calendar [2]. The Council, SC, and CTC meet there.

4.2 Summer and Winter Schools

Technical Committee 23 is specifically tasked with supporting the education of young glass technologists. Over many years short course teaching has been undertaken throughout the world using expertise available within ICG. This approach crystallized during the EFONGA project (2005–2009) in the initiation of an Annual Summer School based at a single site (Montpellier, France). It uses a core group of lecturers with new teachers recruited annually to give each school a distinctive flavor.

The following countries have also been represented at some time during the period 1933–2018: Australia (1966–1977; 2008–2014), Egypt (1957–2003), Greece (1984–2017), Indonesia (1981–2003), Ireland (2002–2005), Philippines (1998–2009), Serbia (2008–2015), and Yugoslavia (1970–1992).

The school has evolved as its teachers have learned how best to develop understanding and stimulate a deep interest in the subject. Key aspects are the group project work undertaken competitively during the week and small group tutorials that supplement the 20 lectures. Participants and teachers are encouraged to network, something that can continue into their professional lives, and to question everything. This school is in its 11th year (2019); a major textbook entitled *Teaching Glass Better*

covering both the historical development and central themes of the school was published to celebrate the 10th anniversary in 2018.

Following enthusiasm for extending the schools beyond Europe, a Winter School was run in Shenzhen, China, in 2014 to encourage wider participation from Far Eastern countries. Teaching, by lecturers from the Montpellier School and the local community in China, was in English. The second school ran in Wuhan in

The following countries have also been represented at some time during the period 1933–2018: Australia (1966–1977; 2008–2014), Egypt (1957–2003), Greece (1984–2017), Indonesia (1981–2003), Ireland (2002–2005), Philippines (1998–2009), Serbia (2008–2015), and Yugoslavia (1970–1992).

2016 just before ICG's Shanghai Congress. Subsequent schools have adopted the same venue and the fifth will run in 2019. Generous grants from the Chinese allowed exchange of students between the Montpellier and Wuhan schools in 2018, creating a new and much appreciated dimension to this exercise. Other venues around the world are being considered, and a school focused on optical properties is planned in North America (Laval, Canada) immediately after the 2019 ICG Congress. An unexpected bonus has been the sharing of different teaching styles among the staff.

4.3 Publications

From 1957 the ICG has actively supported publication of bibliographies, reviews, or books with an international flavor. It has always had committees tasked with this role. ICG books in print are housed at the DGG offices in Germany and can be purchased by direct application. They are listed on the ICG web site: www.icglass.org. Of the 50 or so books supported to date, 12 have been multilingual dictionaries, 6 cover chemical analysis/durability measurement methodologies, and another 6 cover

physical properties. Besides, five have been concerned with furnace technology (sensors, regenerators, refractories), two with electrical properties, and two list educational establishments. Two have been histories of ICG. Others have reviewed optoelectronics, biomaterials, crystallization and glass ceramics, electrochemistry, and bubble formation. Books written by members of TC04 (biomaterials), TC17 (history of glass bead making in India), and TC20 (optical properties) are among those recently supported. Finally, three recent texts form a series on “Making Glass Better” and record road-mapping exercises (2010, 2014, 2015); “Teaching Glass Better” (2018) is the most recent addition and has initiated a new direction.

Finally, an attempt in 1950 to produce an ICG journal foundered because its remit overlapped with journals already published by its NPOs.

4.4 Prizes Awarded

One way in which ICG supports the global glass community, particularly its younger members, is to encourage and support excellence by offering prizes. The Woldemar A. Weyl International Glass Science Award was established in 1976 by the Pennsylvania State University and ICG. It honors Prof. Weyl (1901–1975) who was well known internationally as an imaginative and innovative scholar and teacher. Professor Weyl wished to give his young associates every opportunity to participate in scientific meetings. Therefore, the Award recognizes outstanding, innovative, young glass scientists, preferably not over 35 years old, by funding a lecture to be given at each ICG Congress. Anyone can submit nominations to the Chair of the Glass and Optical Materials Division of the American Ceramic Society (see Table 9).

The ICG Prize in Memory of Prof. Vittorio Gottardi was instituted in 1986. It celebrates Prof. Gottardi (+1985), ICG President from 1984 to his death, in October 1985, and recognizes meritorious research, development, teaching, writing, management, or commercial achievements in the field of glass. The spectrum of activities qualifying for recognition is purposely broad so that workers throughout the glass community are eligible. The Prize is presented annually to a person not past their 39th birthday when nominated and not past their 40th at the date of the award. Nominations are submitted by NPOs (Table 10).

To recognize outstanding lifetime contributions to the international glass community, the ICG established the ICG President’s Award in 1994, in part to honor its first president, Prof. Turner. Council members nominate deserving individuals (Table 11).

Inaugurated in 2002, the Turner Award recognizes those who have made a noteworthy contribution to ICG’s

Table 10 Gottardi Prize winners.

5 Perspectives

Dramatic changes in society require that ICG “moves with the times.” Already the Globalization of Industry has blurred the boundaries of the domains of activity of NPOs. So the trend to populate new membership categories will continue and influence ICG. Countries with

little or no representation must be encouraged to participate.

ICG is an ideal platform for industry–academia collaboration and for interdisciplinary projects, as EFONGA showed. Conversely both industrial and academic workers are under growing time pressures and tighter financial constraints. TCs are meeting less often and progressing more slowly. ICG needs to demonstrate the added value

of involvement to TC members, and their employers in industry and academia, by publishing exciting research in high impact journals, generating excellent texts (road-maps, standards) and working on international issues such as energy efficiency, sustainability, and environmental protection. Ways of financing increased activity and enhancing communications are being investigated via an internal exercise called Project 2030.

ICG already offers educational support to the next generation of workers, but this needs extending. Involving younger participants in TCs can support their development and enliven TC activities. The recent creation of a Young Person's Committee has already led to the introduction of Mentoring Events at the most recent ICG Annual Conferences (2017, 2018) and further developments are planned.

Section X. History

This section devoted to a broad history of glass cannot begin without a mention of Pliny's legendary account of Phoenician merchants who observed a melting reaction between the natron blocks they took to support their cauldron and the sand of the beach where they set a fire to prepare their meal ([1]; Appendix X.A). Glass was in fact nearly 2000 years old at Pliny's time. As wittily noted by the eminent glassmaker Georges Bontemps (1799–1883), if not entirely legendary the story would rather have been that of traders en route to deliver their cargo to some local soda-lime silica glass factory [2]!

More informative in Pliny's descriptions are the technical skills displayed by ancient glassmakers who could fetch very high prices for outstanding glass items and who were in addition able to distinguish fake from real gems by a lower density, a lower thermal conductivity (in modern parlance), or the presence of bubbles and other defects. And Pliny also left interesting reflections on the dual creative and destructive effects of fire, on obsidians (opsian), on the reputation of Egyptian soda, as well as doubts concerning the veracity of Petronius' famous account of flexible glass in the *Satyricon*.

In Eurasia, glass has been exchanged over long distances for 2 million years in the form of obsidian whose unique sharpness made it a highly valued commodity. Obsidians are not so common volcanic rocks. Nowadays, what make them specially important is that their trace-element compositions constitute a fingerprint of their geographical origin, which may have been hundreds or even thousands of km from the sites where obsidian artifacts are now found. In the first chapter, R. Tykot describes how prehistoric trade patterns in western Mediterranean, Near East, and Latin America can be reconstructed from trace-element analyses of obsidians,

which can nowadays be made on the spot, thanks to modern X-ray fluorescence instrumentation; also summarized is the information that can be drawn on ancient cultures from studies of the wear or weathering of the artifacts themselves (Chapter 10.1).

For a very long time, glass had been a familiar material when glassmaking was invented less than four millennia ago in the Near East and Egypt. Although its origins remain clouded in mystery, they were likely related to ceramic or metallurgical activities. These resulted in a diversity of chemical compositions that is well documented throughout time and space by the thousands of analyses now available [3, 4]. In any case, the beginnings of glassmaking attests to the long and tenacious efforts driven by the sheer curiosity of artisans who were obviously unable to guess the nature of the products that would be the long-term outcome of their work. Clearly, aesthetic interest was first raised by the vivid colors and gem-like aspect of glass. It gave rise to the variety of coloration methods reviewed by A. Shortland and P. Degryse who also describe how chemical and isotopic analyses of ancient artifacts can yield reliable information on the provenance of the raw materials used, production processes, and places of production (Chapter 10.2).

At the turn of the millenia, of particular importance were the inventions of glass blowing and of transparent glass made from quartz sand and naturally pure sodium carbonate salts called *natron*. Glass production then became a real industry with the establishment of the first-ever world market whereby, thanks to clear competitive advantages, large amounts of glass produced mostly in the Levant were exported throughout the Mediterranean area and beyond either as ingots (Figure 2) or finished products. The various facets of this activity are

addressed by I. Freestone, beginning with melting tanks of up to 20-t capacity and continuing with the chemistry of the glass and its subsequent transparency, coloration, or opacification, its transformation in secondary workshops and the recycling of this valuable resource as cullet (Chapter 10.3).

In Antiquity, glassmaking did not fail to attract the philosophers' interest. Along with the transformation of plain earths into a substance looking like gems, the

kinship of molten glass with metals and the role later played by glass in emerging alchemy were good reasons for pondering over its nature and its place in the philosophy of matter. From early reflections made in Mesopotamia and in Egypt on glasses as molten precious stones, the issue was taken over in Greece. From Empedocles to Plato and Aristotle, the attempts summarized by M. Beretta aimed at explaining the formation of glass in terms of elementary constituents or of *qualities*; they

entertained a close relationship of glass not only with alchemy but also with gem counterfeiting within a theoretical framework that would exert a long-term influence through its transmission to Byzantium (Chapter 10.4).

Of course, these ancient ideas ceased long ago to be relevant to glassmakers. In contrast, the various processes devised in Antiquity for shaping glass have been continuously used since then and are still those of contemporary artists and makers of highly priced crystal-glass items. Before the shaping possibilities offered by the new material were understood, the first forming processes were inspired by ceramic practices. As reviewed by M. Stern, who also pays attention to the social and working contexts of ancient glassmaking, these processes were progressively complemented by casting, pressing, molding, blowing, and hot- and cold-decorative techniques, which could then be combined to shape outstanding items such as gold, cameo, and cage-cup glass pieces; before the invention of the *pontil*, however, blowing did not spread as fast as often assumed because previous processes were already efficient economically (Chapter 10.5).

Coatings, which are an important feature of modern glassmaking, are not a recent invention at all. Under the names of *enamels* (deposited on smooth surfaces) and *glazes* (on porous ones), they were already deposited in Antiquity as thin layers to modify surfaces either for hardening or tightening them or for aesthetic reasons. Like for modern coatings, the most important problems to be solved, described by Ph. Colomban, were (i) to ensure first the wetting of the metal, glass, or ceramic substrate by the precursor powders and, then, a close thermal expansion match between the coating and substrate to avoid either peeling or cracking, and (ii) to find the appropriate agents for coloring or opacifying thin layers; empirically, these problems were solved in a great many different ways throughout the centuries and in various parts of the world as illustrated by the Chinese *celadons*, the Japanese *Raku*, the European porcelains as well as by contemporary production (Chapter 10.6).

In Europe, glassmaking suffered from the fall of the Roman Empire caused by the Barbarian invasions of the fourth and fifth centuries, especially because primary fabrication was lacking. Given that much of antique production is known through finds made in graves or from the Pompei catastrophe, a consequence of the Church prohibition to bury items with the dead is that little is known about European glass production in the early Middle Ages. Whereas written sources document glass production in Venice from the late tenth century, chemical analyses of archeological glass fragments point to a continuous production from Roman times with an important change from natron to plant-ash glasses between the ninth and thirteenth centuries. As documented by M. Verità, the efforts subsequently made to improve composition, for example, by the use of quartz pebble for silica

and carefully washed plant ash for soda, resulted in the invention of the famous clear *cristallo* and of colored specialty products; these made Venice the world leader in glass production from the fifteenth to the seventeenth century and thus prompted imitators to produce their own pieces *à la façon de Venise* (Chapter 10.7).

By far the most extensive body of ancient glass artifacts is exhibited by the stained glass of church windows. Their earliest mentions are found in texts from Late Antiquity. Despite the great many causes of destruction throughout the ages of such a fragile material, extant windows are remarkably abundant in Europe from the thirteenth century. As reported by J.M. Parker and D. Martlew, their religious message could be readily understood in the form of vividly colored images made of flat glass produced by the two already ancient *crown* and *cylinder* processes, whereby glass was first blown to keep a fire polish before being flattened and cut into pieces that are assembled with soft lead *comes*; beginning with *grisaille* and silver staining, other ways to modify the glass color and texture were then developed over the centuries to produce new styles or to restore ancient pieces, sometimes so well that up-to-date analytical means are needed to distinguish original from restored parts (Chapter 10.8).

Glass had to wait until the eighteenth century to recover in European households the importance it had in Roman times. With low production volumes, melting and forming processes basically remained those designed in Antiquity. The first important changes described by M.-H. Chopinet and P. Richet were the substitution of coal for wood as a fuel in England in the early seventeenth century and the invention of the table-casting process for plate glass half a century later in France; but it was only from the beginning of the nineteenth century that the birth of both modern chemistry and thermodynamics triggered a continuous string of improvements to save energy with regenerators, to design more efficient furnaces, to switch from pot to tank melting, to improve chemical composition, and to produce flat, plate, and container glass with the first mechanical processes designed at the beginning of the twentieth century (Chapter 10.9).

That glass has been the science material *par excellence* is then justified by P. Richet who points out its original importance in optics and alchemy and its subsequent key roles in the exploration of the universe with the telescope and the microscope, in the design of thermometers, barometers, and other instruments that were at the roots of the scientific revolution, in chemistry, in the birth of electrical science, and in the research that began with the cathode-ray tube and eventually led to subatomic physics; all of these fields benefited along the way from progressively improved glasses in terms of both homogeneity and composition (Chapter 10.10).

The history of glass science is the next topic dealt with. Like glassmaking processes, conceptions of the nature of

glass changed little from Antiquity to the seventeenth century, tells P. Richet in a story where, given the lack of such an account in the literature, care has been taken to bring to light the work made by numerous workers throughout the ages; although the real beginnings of glass science can be dated to the picture of the glass transition given by Descartes, a distinct glass science relying on concepts specifically designed to account for the special properties of glass-forming liquids appeared only in the early twentieth century when new experimental tools became available to investigate their properties and determine their structures (Chapter 10.11).

Finally, we note that pure art is beyond the scope of the Encyclopedia in spite of a rich tradition that dates back to the very beginnings of glassmaking. The reason is that the original insights on glass *as a material* that can be drawn from studies of past items have been summarized in previous chapters so that a review of ancient or modern masterpieces from an art-history perspective would add little in these scientific and technical respects. Hence, it is better to illustrate the glassmakers' artistry with a selection of items that covers 25 centuries of activity (Figure 1), and to draw the attention of the reader interested to a few standard reference books on these topics [7–12].

It has nonetheless been deemed appropriate to conclude the *Encyclopedia* with a chapter on Glass museums or museums holding significant glass collections. As noted by D. van Kerssenbrock-Krossigk, these collections were first made by the powerful or wealthy of Antiquity who considered glass vessels and sculptures as treasures: these collectors began a tradition that was pursued by princely houses before benefiting from the general expansion of museums in the nineteenth century and, afterward, from the specialization of some in the decorative or regional arts; more recently, interest has in addition been paid not only to conservation and exhibitions, but also to teaching and to technical and scientific investigations of glass collections (Chapter 10.12).

Appendix X A Pliny's Famous Account of the Origin of Glass in His *Natural History*

LXV. That part of Syria which is known as Phoenicia and borders on Judea contains a swamp called Candebia amid the lower slopes of Mount Carmel. This is supposed to be the source of the River Belus, which after traversing a distance of 5 miles flows into the sea near the colony of Ptolemais. Its current is sluggish and its waters are unwholesome to drink, although they are regarded as holy for ritual purposes. The river is muddy and flows in a deep channel, revealing its sands only when the tide ebbs. For it is not until they have been tossed by the waves and cleansed of impurities that they glisten. Moreover, it is only at that moment, when they are thought to be affected by the sharp, astringent properties of the brine, that they become fit for use. The beach stretches for not more than half a mile, and yet for many centuries the production of glass depended on this area alone. There is a story that once a ship belonging to some traders in natural soda put in here and that they scattered along the shore to prepare a meal. Since, however, no stones suitable for supporting their cauldrons were forthcoming, they rested them on lumps of soda from their cargo. When these became heated and were completely mingled with the sand on the beach, a strange translucent liquid

flowed forth in streams; and this, it is said, was the origin of glass.

LXVI. Next, as was to be expected, Man's inventive skill was no longer content to mix only soda with the sand. He began to introduce the magnet stone also, since there is a belief that it attracts to itself molten glass no less than iron. Similarly, lustrous stones of many kinds came to be burnt with the melt and, then again, shells and quarry sand. Authorities state that in India glass is made also of broken rock-crystal and that for this reason no glass can compare with that of India. To resume, a fire of light, dry wood is used for preparing the melt, to which are added copper and soda, preferably Egyptian soda. Glass, like copper, is smelted in a series of furnaces, and dull black lumps are formed. Molten glass is everywhere so sharp that, before there is the least sensation, it cuts to the bone any part of the body on which it splutters. After being reduced to lumps, the glass is again fused in the workshop and is tinted. Some of it is shaped by blowing, some machined on a lathe, and some chased like silver. Sidon was once famous for its glassworks, since, apart from other achievements, glass mirrors were invented there.

This was the old method of producing glass. Now, however, in Italy too a white sand which forms in the River Volturno is found along 6 miles of the seashore between Cuma and Literno. Wherever it is softest, it is taken to be ground in a mortar or mill. Then it is mixed with three parts of soda, either by weight or by measure, and after being fused is taken in its molten state to other furnaces. There it forms a lump known in Greek as "sand-soda." This is again melted and forms pure glass, and is indeed a lump of clear colorless glass. Nowadays, sand is similarly blended also in the Gallic and Spanish provinces. There is a story that in the reign of Tiberius there was invented a method of blending glass so as to render it flexible. The artist's workshop was completely destroyed for fear that the value of metals such as copper, silver, and gold would otherwise be lowered. Such is the story, which, however, has for a long period been current through frequent repetition rather than authentic. But this is of little consequence, seeing that in Nero's principate there was discovered a technique of glass-making that resulted in two quite small cups of the kind then known as "petroti" or "stoneware" fetching a sum of 6000 sesterces.

LXVII. In our classification of glass we include also "obsian" ware, so named from its resemblance to the stone found by Obsius in Ethiopia. This stone is very dark in color and sometimes translucent, but has a cloudier appearance than glass, so that when it is used for mirrors attached to walls, it reflects shadows rather than images. Gems are frequently made of it, and we have seen also the solid obsidian statues of (the Roman emperor) Augustus of Revered Memory, for the substance can yield pieces

bulky enough for this purpose. Augustus himself dedicated as a curiosity four elephants of obsidian in the temple of Concord, while the Emperor Tiberius for his part restored to the cult of the Sun-god at Heliopolis an obsidian statue of Menelaus which he found included in a legacy from one Scius who had been governor of Egypt. This statue proves that the origin of the stone, which is nowadays misrepresented because of its similarity to the glass, is of an earlier date. Xenocrates records that obsidian is found in India, in Italy within the territory of the Samnites, and in Spain near the shores of the Atlantic. There is also the artificial "obsian" glass which is used as a material for tableware, this being produced by a coloring process, as is also the case with a completely red, opaque glass called in Greek blood-red ware. There is, furthermore, opaque white glass and others that reproduce the appearance of fluorspar, blue sapphires, or lapis lazuli, and, indeed, glass exists in any color. There is no other material nowadays that is more pliable or more adaptable, even to painting. However, the most highly valued glass is colorless and transparent, as closely as possible resembling rock-crystal. But although for making drinking vessels the use of glass has indeed ousted metals such as gold and silver, it cannot bear heat unless cold fluid is first poured into it; and yet glass globes containing water become so hot when they face the sun that they can set clothes on fire. Pieces of broken glass can, when heated to a moderate temperature, be stuck together, but that is all. They can never again be completely melted except into globules separate from each other, as happens in the making of the glass pebbles that are sometimes nicknamed "eyeballs" and in some cases have a variety of colors arranged in several different patterns. Glass, when boiled with sulphur, coalesces into the consistency of stone.

LXVIII. And now that we have described everything that depends upon Man's talent for making Art reproduce Nature, we cannot help marveling that there is almost nothing that is not brought to a finished state by means of fire. Fire takes this or that sand, and melts it, according to the locality, into glass, silver, cinnabar, lead of one kind or another, pigments, or drugs. It is fire that smelts ore into copper, fire that produces iron and also tempers it, fire that purifies gold, fire that burns the stone which causes the blocks in buildings to cohere. There are other substances that may be profitably burnt several times; and the same substance can produce something different after a first, a second, or a third firing. Even charcoal itself begins to acquire its special property only after it has been fired and quenched: when we presume it to be dead, it is growing in vitality. Fire is a vast, unruly element, and one which causes us to doubt whether it is more a destructive or a creative force.

10.1

Obsidian in Prehistory

Robert H. Tykot

Department of Anthropology, University of South Florida, Tampa, FL, USA

1 Introduction

According to the *Natural History* of Pliny the Elder [1], obsidian was a kind of glass found in Ethiopia by a Roman explorer named Obsius, a “stone very dark in color and sometimes translucent” but which “has a cloudier appearance than glass, so that when it is used for mirrors attached to walls it reflects shadows rather than images. Gems are frequently made of it.” At Pliny’s time, however, obsidian had already been long sought after as indicated, for instance, by its use for the pupils of Tutankhamun’s eyes in the funerary mask of the young pharaoh.

Obsidian is in fact a rather rare type of volcanic rock of little importance in the modern world, even to geologists (Chapter 7.2). It thus is infrequently listed in the indexes of geology reference volumes, even those specifically devoted to igneous rocks and their classification. Today, obsidian is used for some eye and heart surgical operations due to the fast healing rates of glass, and as a gemstone for jewelry and decorative objects where it may come from very far away: on the Italian island of Pantelleria, the geological-type location for Pantellerite, the irony is that a gift shop sells many items from Pachuca (Mexico)!

Of much greater significance is that obsidian was highly valued by prehistoric people in the form of lithic (flaked) materials that are among the most common artifacts in the archaeological record. They were the product of several distinct actions: acquisition of the raw material, preparation of a core for flaking, primary trimming, secondary trimming and shaping, use, maintenance or modification, and disposal. When flaked, obsidian produces extremely

sharp cutting edges and is often superior to chert, flint, jasper, and other lithic materials for cutting materials such as animal flesh and nonwoody plants.

Obsidian use for stone tools dates back to nearly two million years ago at early hominin sites in Ethiopia where standardized tools were produced in the Lower Pleistocene Acheulean. Significant quantities of obsidian have been found at later archaeological sites hundreds of kilometers away from their geological source, even when alternate lithic materials were available at lesser distances. These findings indicate that obsidian was selected for use because of its particular physical and visual properties and that the exploitation of such a valuable rock was by the way probably the cause of the initial human settlement of islands such as Lipari or Pantelleria.

Obsidian is playing a particularly special role in archaeology for several reasons: (i) it can be easily identified as a nonlocal material; (ii) it is relatively easy to determine the specific source of archaeological specimens through chemical analysis; (iii) its hydration, which develops over time, can be used to date directly the production of tools; (iv) its broad spatial distribution provides a means for investigating the interaction of different social or cultural groups, and to speculate on the parallel movement of materials that are not as well preserved in the archaeological record; and (v) it gives us the opportunity to examine the chronological developments and the dynamic nature of its usage by prehistoric peoples, and the economic and social conditions under which this usage occurred.

Starting in the early 1960s, elemental analysis of obsidian artifacts has been successful in identifying their geological source [2]. Since then numerous such studies have been performed around the world, using many different methods of analysis, so that the principles behind obsidian analysis and sourcing are well established [3]. On the other hand, development of nondestructive and portable instruments has overcome the restrictions imposed on obsidian

Reviewers: K. P. Freund, Liberal Arts, Indian River State College, Fort Pierce, FL, USA

M. D. Glascock, Department of Anthropology, University of Missouri, Columbia, MO, USA

analyses by many museums and governmental agencies, greatly enhancing the number of artifacts analyzed [4, 5].

To review these various features, this chapter will first summarize the geological context of obsidian formation and the reasons for their compositional differences. The main uses of this material, its resulting wear, and the manner artifacts can be dated will then be described briefly. More importance will be given to chemical compositions, which may be used to identify the geological origin of obsidian artifacts. The complex pattern of these sources will be illustrated for Europe and particularly for the western Mediterranean. Some examples of the conclusions drawn from these studies for prehistoric trade and ancient socioeconomic systems will be presented.

2 Geological Formation, Properties, and Sources

Obsidian is a naturally occurring glass with silica contents of 65–80 mol % and relatively high alkali contents (8–10 mol % of $\text{Na}_2\text{O} + \text{K}_2\text{O}$). There are two varieties, termed *calc-alkaline* obsidian (with high SiO_2 and relatively high CaO contents), and *peralkaline* (if the alkali total exceeds the Al_2O_3 content, also lower SiO_2 and CaO), deriving both from parent *rhyolitic* magmas (Chapter 7.2). Especially, the more typical obsidian with 75–80 mol % SiO_2 are so strongly polymerized and viscous that they cannot always complete their ascent up to the Earth's surface (Chapter 7.2). When they do so, instead of crystallizing as granite at shallow depths, their high viscosity then makes vitrification possible even for large blocks upon rather slow cooling.

That each obsidian source has its own chemical fingerprint in terms of minor and trace elements is the result of complex geological phenomena. First, SiO_2 -poor buoyant magmas form at depths of at least 100 km by partial melting of mantle rocks whose elemental composition can vary from one place to another. Then, during their ascent to the surface, magmas undergo a long process termed *magma differentiation* through which they give rise to residual melts progressively enriched in SiO_2 , alkali oxides, and some trace elements as a result of partial crystallization of dense, SiO_2 -poor minerals such as olivines $[(\text{Mg},\text{Fe})_2\text{SiO}_4]$ and pyroxenes $[(\text{Ca},\text{Mg},\text{Fe})\text{SiO}_3]$. In addition, chemical and physical interactions with a variety of surrounding fluids and rocks take place during the slow ascent of the magma so that in the end, even obsidian from successive flows of the same volcano can have different chemical fingerprints.

But geological obsidian is not as homogeneous as modern human-made glass because it frequently includes crystals and bubbles. In the form of tiny particles, magnetite (Fe_3O_4) is, for instance, often the first crystal to

form. Whether as isolated spherulites or as thick beds within the obsidian, crystals reduce the stone's ability to be flaked into a tool, as does exposure to groundwater that causes over long periods of time the formation of a white, hydrated amorphous phase called *perlite*.

In regions with the appropriate geological and geochemical characteristics, nearly all sources of usable obsidian are thus less than 20 million years in age. They are found in many places along the mountain chains of western North America and the Andes of South America; in southeast Europe, Anatolia, and the Middle East; on several Mediterranean islands; in East Africa; in northeast Asia and Japan; and on islands of Southeast Asia, Oceania, and the Pacific (Figure 1). Whether the obsidian is in primary or secondary geological contexts, these sources vary considerably in the magnitude and extent of the obsidian flow and in the size and quality of the obsidian blocks that are accessible (Figure 2).

Elemental composition, crystallinity, and the redox state of transition elements affect the color and transparency of obsidian, which are important visual characteristics and factors in their selection for use. Most are gray-to-black, while some are green, brown, and tan. A few examples of red, blue, yellow, and orange are also known. Obsidian is commonly dark because of the presence of nanometric crystals of iron oxides whose varying stoichiometries yield a variety of gray/black or mahogany hues. Like that of thick window glass, the green hue of peralkaline obsidian is due to the presence of ferrous Fe^{2+} at high concentrations (cf. Chapter 6.2). But since there is movement of the Earth's crust and cooling of the lava takes place under uncontrolled temperature and redox conditions, the microstructure of obsidian, and thus its color and transparency, can vary within a single volcanic complex.

3 Obsidian Use in Prehistory

As a glass, obsidian is very sharp and brittle, with a Mohs hardness of 5.0–5.5. This gives it both advantages (e.g. utility for cutting) and disadvantages (e.g. easy breakage) when compared with other stone material. First and foremost, it was used for stone tools, but also in some cases for jewelry or other decorative uses. Compared with other stones (flint/chert, quartzite, rhyolite, etc.), obsidian had significant cutting advantages, thanks to its glassy sharpness, especially for meat, hides, and other organic materials. Along with its visual distinctions, these characteristics often led to obsidian's selection over other available raw materials and to its resulting transport over great distances.

Obsidian from mainland sources was utilized very early on, with procurement ranges of at least 100 km for Lower Paleolithic people in east Africa and Eurasia. Including those in Japan, island sources appear to have been first

Figure 1 World map of obsidian sources utilized in ancient times. In the western Americas and eastern Asia, obsidians form in the geological context of compressive subduction zones by differentiation of andesite magmas. In other regions, they form from basaltic magmas in the extensive contexts of plate separation.

Figure 2 Balata dei Turchi (southern side of Pantelleria, Italy) primary obsidian flows (three arrows on left), with secondary deposits on slope in the lower right. Peralkaline obsidian, dark green, opaque.

used in the Upper Paleolithic (ca. 40–10 kya). Obsidian sources in the Americas were utilized starting with its Pre-Clovis inhabitants (>13 kya). In the Mediterranean, all of the island obsidian sources were regularly in use from the Neolithic period.

Some geological sources are fairly recent, coming, for example, from the volcanic outcrops in Lipari formed

about 8.5 kya ago [6], which were thus unavailable to the earlier residents of Sicily and peninsular Italy.

The discovery of obsidian artifacts has always been of importance to archaeologists, especially when there was no nearby geological source, as it indicates some kind of long-distance mobility or contact. The quantity or percentage of lithic artifacts made of obsidian, along with its

visual, physical, and chemical properties may be highly informative about ancient societies and how/why they obtained the raw material, produced finished objects, how and why they were used, and in what contexts they were left behind. In addition, other materials likely were transported in parallel to the obsidian.

4 Obsidian Studies

4.1 Typo-Technology

Typological and technological studies of lithic finds are necessary for full socioeconomic interpretations of

obsidian (and other stone tool) production and use. Starting with natural obsidian blocks, direct or indirect percussion may have been used for production of cores, often not far from the geological source, with the side effect of leaving behind large flakes and shatter (Figure 3). The cores may have been of specific types, for example, polyhedral blade cores, distributed over great distances to secondary production locations. The presence of smaller debitage and spent cores indicates such local production of tools. Certain tools were also retouched to enhance cutting properties. The production of stone tools requires some experience, as well as the intention to make specific types such as blades, scrapers,

Figure 3 Obsidian blocks (up to 40 cm in length), cores (up to 15 cm), blade (20 cm) and arrowheads (4–8 cm) from different parts of the Mediterranean.

and arrowheads, which would have been mounted on wooden or bone handles.

4.2 Use-Wear Studies

Macroscopic and microscopic examination of wear patterns on obsidian may be done to determine their actual usage, adding significantly to their archaeological context and associated materials [7]. In general, these patterns differ depending on the hardness (soft, medium, and hard) and siliceousness (animal, vegetal, and inorganic) of the worked material. Use-wear fractures are recorded as being absent, or at a rate of occurrence with fractures classified as flakes (conchoidal fractures), snaps, or steps. The distribution of edge-wear fractures is recorded as random or regular, and light or heavy, and complements width and edge rounding by wear fracture. The most likely function of a tool is determined from the type of use-wear, its frequency, size, and distribution. Owing in part to variations in the physical properties of obsidian from different geological sources, along with the actual use methods employed, experimental studies have been conducted in different parts of the world. In particular, it has been shown that there are quantitative and qualitative differences in wear patterns between obsidian from different geological formations, which may have influenced selection when material from more than one source was accessible [8].

4.3 Dating Methods

Obsidian hydration has been used in many parts of the world as a method to determine the date at which a tool was made from the rate of diffusion of water onto a freshly exposed surface. With a methodological approach begun in the 1960s, the thickness of the hydration rim or band may be measured by high-powered microscopy of a thin section (ca. 30 μm thick) [9]. The problem is that the rate of rim growth is affected by temperature, humidity, and pressure, as well as by the specific geochemistry and physical properties of the obsidian. To produce accurate age estimates, the recommended calibration thus consists of depositing a “standard” of freshly flaked obsidian in the ground for one year at a depth similar to that of the archaeological stratum along with a measurement device to determine the effective hydration temperature (EHT). The implicit assumption made is of course that these underground conditions did not change markedly since the obsidian was buried.

Another dating approach relies on secondary-ion mass spectrometry for depth profiling the hydration rim by direct measurements of the H concentration. Equations for the diffusion process are still being developed, but this analytical method is nondestructive and has the

additional advantages of incorporating the kinetics of the diffusion mechanism for water molecules and determining the saturation layer. Even more recently, infrared photoacoustic spectroscopy (IR-PAS) is being developed as an obsidian-dating method [10].

5 Provenance Analysis Methods

The characterization of obsidian begins with macroscopic observations and measurements of physical properties including color, transparency, density, and the presence of large crystals (phenocrysts). Whereas these features might have been important for obsidian users, they often are insufficient by themselves for reliably defining individual origins when multiple sources of obsidian exist in a particular region. One exception to this rule is the regional presence of a single peralkaline (green) obsidian source, for example, Pachuca in Central America and Pantelleria in the western Mediterranean. Another exception is found when there is a single source with large “snow flake” phenocrysts of cristobalite, for example, Giali in the Aegean. In some cases, microscopic analysis may differentiate sources from features such as crystal dimensions, frequency, and orientation patterns (streaks, linear, and random).

Whereas many methods of scientific analysis have been successful in distinguishing among sources in a particular region, the analysis of archaeological artifacts is often limited if the method is destructive or costly and if the artifacts must be taken outside a museum since museums and government agencies increasingly forbid destructive methods and limit analyses in external laboratories. Some countries do not allow artifacts to be sent beyond their borders, even if they do not have the analytical instrumentation needed.

The conservation and preservation of archaeological materials is actually of great long-term importance, in particular for obsidian put on display in museums, or involved in multiple studies including technology, typology, use-wear, and dating, as well as the large assemblages stored in warehouses. And even though the depth and quantity of obsidian artifact analyses has changed significantly since the first studies of the 1960s along with the development of many instrumental methods of analysis (Table 1), they vary considerably in different parts of the world because research funding for archaeology is generally limited relative to other disciplines.

A broad variety of analytical methods have nonetheless been successful in distinguishing geological obsidian sources from elemental or isotopic composition, geological dating, and magnetic properties. Within a single region, the volcanic events that produced obsidian may

Table 1 List of analytical sourcing methods.

Method	Sample ^a	Measurements	Limitations
<i>Dating</i>			
Argon–Argon (Ar–Ar) or Potassium–Argon (K–Ar) dating	Yes	Date of formation	
Fission-track (FT) dating	Yes	Date of formation	
<i>Isotopes</i>			
Thermal ionization mass spectrometry (TIMS)	Yes	Sr isotope ratios	
<i>Magnetic properties</i>			
Susceptibility and magnetometer instruments	No	Magnetic susceptibility, remanent magnetization	Need outcrop database
<i>Elemental</i>			
Atomic absorption spectroscopy (AAS)	Yes	Major/trace elements	
Electron probe microanalysis (EPMA)	Maybe ^a	Major/minor elements	Surface analysis
ICP mass spectrometry (ICP-MS) (quadrupole)	Yes	Major/trace elements	
With laser ablation (LA-ICP-MS)	Maybe ^a	Major/trace elements	Surface analysis
ICP atomic/optical emission spectroscopy (ICP-AES, ICP-OES)	Yes	Major/trace elements	
Instrumental neutron activation analysis (INAA)	Yes	Trace elements	Few major elements
Optical emission spectroscopy (OES)	Yes	Major/trace elements	Few major elements
Proton-induced X-ray/Gamma ray emission (PIXE/PIGME)	Maybe	Major/trace elements	Surface analysis
Scanning electron microscopy (SEM-EDS)	Maybe ^a	Major/minor elements	Surface analysis
X-ray fluorescence (XRF) (energy dispersive)	Maybe ^a	Major/trace elements	Surface analysis
Portable (or handheld) X-ray fluorescence (pXRF)	No	Major/trace elements	Surface analysis

^a A sample must be taken for solution, powder, or to fit within a chamber (depending on the size).

differ by hundreds of thousands or millions of years and be dated precisely by potassium-argon dating, which relies on the decay of ^{40}K into ^{40}Ar with a half-life of 1.25×10^9 years, or by the more sophisticated ^{40}Ar – ^{39}Ar technique. These methods, however, are not only expensive but also destructive so that they are rarely used on artifacts. Fission-track dating is another method that is based on the density of fossil damage tracks left within the atomic network of the artifact through atom bombardment by the alpha rays emitted when uranium isotopes decay radioactively. It has been used to some extent in determining formation ages, but the total number of artifacts tested is limited. Strontium isotopes (87/86) and magnetic properties (conferred by the permanent magnetization acquired by magnetite crystals upon cooling below their Curie temperature in the Earth's magnetic field) also have been shown to be successful, but remain rarely used.

The compositional homogeneity of a given obsidian source, coupled with significant differences between

different flows, has resulted in highly successful differentiation from certain elements, either major (i.e. with oxide abundances higher than 1 mol %) or in trace at lower contents. Referring to Chapter 5.1 for a review of these analytical methods, we, for instance, note that since the 1970s both X-ray fluorescence (XRF) and neutron activation analysis (INAA) have been widely used in obsidian studies. Inductively coupled plasma mass spectrometry (ICP-MS) methods were added in the 1990s (first archaeological use of ICP-MS presented by the author at a conference in 1991); and portable (including handheld) XRF in the 2000s (Figure 4). Notwithstanding potential limitations regarding transport and destructivity, the analytical method selected for archaeological projects is often based on availability in local institutional facilities and on the cost involved. Nevertheless, obsidian sources can often be separated from simple X – Y or multivariate graphs of selected elements. For example, in both Mesoamerica and in the Aegean/Central Anatolia, scatter plots with just Sr, Rb, and Zr clearly separate the existing groups [11, 12]).

Figure 4 An obsidian sample sitting on a portable XRF instrument for the desktop nondestructive analysis of trace elements. The four most intense fluorescence bands shown on the computer screen are those of Fe ($K_{\alpha 1}$), Rb (K_{α}), Y (K_{α}), and Zr (K_{α}).

6 The Issue of Obsidian Sources: The European Region

For Europe, obsidian sources are limited to the Carpathian Basin (Slovakia, Tokaj Mountains of northeastern Hungary, and southwestern Ukraine); the Italian islands of Lipari, Palmarola, Pantelleria, and Sardinia; and the Greek Aegean islands of Melos, Giali, and Antiparos. The nearest other sources are in central and eastern Anatolia and the Caucasus, and on Tenerife in the Canary Islands.

For the central Mediterranean obsidian sources, there is considerable variation in color, transparency, and other visual characteristics, which may allow assignment of artifacts to a specific island, depending on the location and time period. Whereas Pantelleria obsidian is the only green (peralkaline) source, chemical analysis is still necessary to distinguish among the multiple subsources utilized there whose products were transported then to Sicily, Malta, and Tunisia. Lipari obsidian exists in both a highly glassy and transparent form (scale 4–5 out of 5) and in a mostly opaque form (scale 0–1) with numerous plagioclase feldspar $[(Ca_xNa_{1-x})Al_{1+x}Si_{3-x}O_8]$ phenocrysts. In Sardinia, the situation is more complex because of the existence of several Monte Arci subsources

with a variety of features [13]. The transparent SB2 (4–5 out of 5) is similar to type SA, and even to Lipari obsidian. SC sources are opaque and can be distinguished from type SA, which is transparent (4 out of 5), but not from SB1. Obsidian from Lipari and from these three Monte Arci subsources have been found at Neolithic sites in peninsular Italy, requiring scientific analysis for positive identification. In later periods (Copper and Bronze Ages), the SB1 and SB2 subsources appear not to have been used very much at all, so that a reasonable estimate of the percentage SA vs. SC may be made visually, albeit with some caution.

Elemental analysis, however, is highly successful in confidently distinguishing all Mediterranean sources and subsources (Figure 5) so that, starting in the 1990s, it has been widely used on large numbers of artifacts. Trace elements such as Nb, Rb, Sr, and Zr will separate all of the sources, as well as five subsources (different flows from the same volcanic complex) each for Sardinia [13] and Pantelleria [14], three each for Lipari [15] and Palmarola [16], and two for Melos [12]. The major elements Si, Al, K, Na, and Ca also can distinguish all of the Mediterranean sources, and some subsources (Figure 6).

The analysis of statistically significant numbers of obsidian artifacts and their assignment to the specific subsources utilized in former times is important in many cases, as these distributions relate to potential differences in the availability, quantity, quality, and features of the raw material. The relative importance of these sources may have changed over time at individual archaeological sites, whereas it also may vary between sites and even within sites based on the context (e.g. residential locations, ritual areas, and burials) [17]. Scientific analysis also is necessary to identify confidently “outliers,” for example, the finding of a few pieces of obsidian from Melos in the Adriatic, or from Sardinia in southern Italy, which have important significance in our understanding of long-distance contacts and trade not only of obsidian but likely other materials as well [18].

7 Obsidian Artifacts Studied in the Western Mediterranean

In the western Mediterranean, extensive studies have been done on obsidian sources and subsources, and on a large number of artifacts. This work includes a geological survey and characterization of the visual, physical, and chemical properties of the Monte Arci obsidian flows on Sardinia [13]. Elemental analysis of geological samples by INAA actually distinguished nine different subsources: SA, SB1a, SB1b, SB1c, SB2, SC1, SC2, and two others of unworkable size [19]. Conducting 200 analyses using

Figure 5 Trace element graph distinguishing Mediterranean obsidian sources.

Figure 6 Multiple flows (subsources) may be distinguished on the islands of (a) Sardinia (Monte Arci) and (b) Melos.

ICP-MS in the early 1990s showed this method equally successful. However, given the tiny amount of SB1 obsidian having been used in the past, and the lack of visual/physical/geographic differences between SC1 and SC2, it was deemed unnecessary to distinguish these subgroups when addressing archaeological hypotheses of usage. Since the SA, SB1, SB2, and SC subsources could be distinguished in electron-microprobe analyses with wavelength-dispersive spectrometers, this minimally destructive and relatively low-cost method was used on 800 Neolithic and Bronze Age period (ca. 6000–1000 BCE) obsidian artifacts. The averaged results obtained on the 30- μ m spots analyzed showed that the three main subsources (SA, SB2, and SC) were widely used in the Early Neolithic period, and that by the Late Neolithic, SB2 was no longer in use while SC dominated most assemblages [17] (Figure 7). This pattern was confirmed by later studies at a large number of different sites in Sardinia and Corsica. Detailed geological survey was also conducted on the other Italian island obsidian sources (Lipari, Palmarola, and Pantelleria). Extensive chemical analyses of geological samples by INAA, LA-ICP-MS, and XRF revealed three subgroups each for Lipari [15] and Palmarola [16], while confirming five subgroups for Pantelleria. Laser ablation ICP-MS was chosen for the analysis of several hundred obsidian artifacts from Pantelleria, Corsica, and mainland Italy sites, due to it being minimally destructive on these small artifacts. The results expanded our understanding of the chronological change in Monte Arci subsurface usage, along with Lipari and Palmarola obsidian in mainland Italy. Research on obsidian in the western Mediterranean continues in southern France, Corsica, and mainland Italy.

Since 2007, a portable handheld XRF spectrometer has been used instead, mostly conducting the analyses within

Figure 7 Bar chart showing source frequencies for Early Neolithic (a) and Late Neolithic (b) sites in the western Mediterranean.

museums or government storage facilities in Sardinia, Sicily, Malta, different parts of mainland Italy, and in Croatia (Figure 8). The portability, nondestructive nature, and relatively lower cost of this instrument has allowed the analysis of over 10 000 obsidian artifacts so far, identifying some surprising patterns of usage, as well as unexpected outliers [5, 18].

One major surprise is the pattern of Lipari and Pantelleria obsidian use on the two main islands of Malta. At the mostly residential site of Skorba on Malta, 79% of the obsidian is from Lipari, and 21% from Pantelleria, whereas at the ritual and burial site of the Brochtorff Circle on Gozo, 72% are from Pantelleria and only 28% from Lipari. This major reversal is likely related to the specific purpose and usage of the obsidian at these two sites. Furthermore, the Pantelleria obsidian came from multiple subsources, while all of the Lipari obsidian was just from the Gabelotto subsurface. Some obsidian artifacts from

the Canneto Dentro subsurface have been identified, however, at sites in Sicily [5].

8 Obsidian Trade and Socioeconomic Systems

The ability to identify specific geological outcrops from which obsidian was utilized in prehistoric times, and to conduct analyses on large numbers of artifacts, has allowed archaeologists to test hypotheses about trade, transport (terrestrial and maritime), and about the socioeconomic systems involved and their changes over time. In this millennium, studies have been flourishing as a means to address broader archaeological research questions devoted, for instance, to procurement methods and spatial distribution, contact between different

Figure 8 Sites with 10 or more artifacts tested (circles by the author, squares by others, triangles by both).

cultural groups, obsidian as a marker of cultural identity, and inferences about the movement of people and other materials [20].

Notable changes have occurred over time, which include access to island sources during the Holocene, development of territorial control and specialist production in later times, and symbolic and ritual use in some

complex ancient and historical societies. One study, on Epi-paleolithic and Early Neolithic obsidian at the site of Kortik in southeast Anatolia, shows heterogeneity on the local and regional scale in raw material selection from different sources and the technology used in this part of the Fertile Crescent [21], whereas another on the Bronze Age in the same region suggests that obsidian cores and

preforms, rather than finished tools, were distributed to local specialists for production of blades [22]. Similar social network issues have been addressed for sites in prehistoric Peru, most likely related to the development of more complex exchange systems by the Nasca, where economic models based on the proximity of obsidian sources have considered elevation and river location changes over time [23]. As for Mesoamerica, changes over the Preclassic, Classic, and Post-Classic Maya period resulted in a highly commercialized economy that does not conform with presumptions often made about preindustrial systems [24]. Archaeological sites are still being discovered and excavated, not just in developing countries in Africa, the Near East, East Asia, and Latin America, but even in settled areas of Europe. One example is the Middle Neolithic site of Terres Longues, at Trets, near Marseilles and the Mediterranean coast, where more than 4500 obsidian artifacts were recently excavated. This accounts for 90% of all obsidian artifacts found so far in France, combining discoveries of obsidian at more than 60 other prehistoric sites [25]. The study of such a large assemblage reinforces the previous evidence that Sardinian type A obsidian dominated this region, while the much higher percentage of obsidian in the lithic assemblage at Terres Longues suggests it might have been a redistribution center.

9 Conclusions and Closing Perspectives

Obsidian has long been an important raw material because its glass-like physical properties made it distributed far away from its geological sources until the advent of metals caused its various advantages to fade away. Scientific analyses have been developed for identifying the origins of individual artifacts and studying their use. More and more studies are multidisciplinary, and integrate the scientific analyses with the archaeological contexts, chronology, lithic typology, and usage studies. But while extensive research has been done in some parts of the world, there remain many areas where the geological sources have not been fully identified and thoroughly studied, and/or large numbers of obsidian artifacts have not yet been analyzed. Doing so for significant-sized lithic assemblages can lead to a fundamental understanding of ancient technological, economic, and cultural practices and how they changed over time.

The International Association for Obsidian Studies (IAOS: <http://members.peak.org/~obsidian>) is a professional organization, and international obsidian conferences have been held in Greece, Japan, Italy, and Hungary. Public interest in obsidian has increased, with

a major museum and center for obsidian studies established in Japan (www.meiji.ac.jp/cip/english/institute/obsidian.html) and one in Italy (www.museossidiana.it), along with many museum exhibits that include obsidian artifacts.

Acknowledgments

I thank many agencies in Italy, France, Malta, and Croatia for allowing my obsidian studies, and the many colleagues who have assisted me with these analyses, while I will always remember Miriam Balmuth who first got me involved in obsidian research more than three decades ago. Thanks are also due to Kyle P. Freund and Michael D. Glascock for their comments on this chapter.

10.2

Ancient Glass, Late Bronze Age

Andrew J. Shortland¹ and Patrick Degryse²

¹ Cranfield Forensic Institute, Cranfield University, Defence Academy of the United Kingdom, Shrivenham, UK

² Earth and Environmental Sciences – Geology, Centre for Archaeological Sciences, Leuven, Belgium

1 Introduction

The exact place where the techniques for the manufacture of glass were discovered is obscure. Even the date of the first glass production is uncertain. What is clear is that by the mid-fourteenth century BCE, glass was relatively common among the elites of Egypt, the Near East, and Greece [1, 2]. Before this time, however, there is a scattering of earlier glass objects stretching back to the third millennium BCE. These findings have been reviewed by several authors but there is some disagreement on the authenticity of certain pieces [1]. Some may be later artifacts that have become mixed with objects from earlier contexts either during the excavation or in early museum collections, whereas other pieces classified as glass may actually be faience.

What is clear, nonetheless, is that man-made glasses have apparently been found in secure contexts from the third millennium BCE and early second millennium BCE [3]. These include a pale yellow-green bead from Tell Judeideh (Syria) that dates from early in the third millennium BCE, a blue glass lump from Eridu (Low Mesopotamia) that has been confidently dated to the Akkadian period (2350–2150 BCE, Figure 1), and scatters of beads from perhaps as early as the Predynastic in Egypt (fourth millennium BCE) and through the Near East a little later. Lucas and Harris [4] stated that there is “no doubt whatsoever that glass beads and tiny glass amulets date from as early as the Fifth Dynasty [in Egypt, 2494–2345 BC], and it is exceedingly probable that they were all of Egyptian manufacture.” But Lilyquist and Brill [5] pointed out that these many beads are often “imperfect” with quantities of

quartz and other minerals entrained within them. They summed up the opinion, which is still held by present scholars, that “glass can only surely be said to appear at the end of the Second Intermediate Period (Dynasties 15/17) or beginning of Dynasty 18, ca. 1550BC.”

Glass, therefore, appears as scattered artifacts in early contexts before what would have been its main invention and the subsequent innovations of its making in the sixteenth century BCE. Because it was a highly valued material, ancient glass may be a rich source of information on Late Bronze Age (LBA) civilization through analyses performed to determine how and where it was made. The second question has in fact a wider interest in archeology than the first: questions of ancient technology are a specialist field, whereas if a precious material such as glass can be shown to have crossed borders, it will reveal connection between powers, exchange, or trade with perhaps much wider implications.

Hence, scientific work on the provenance of glass is now dominating over the investigation of technical questions of production. In this chapter, the various tools used for this purpose will be reviewed. The first is analyses of chemical composition, which have long been practiced to identify specific glass families. Many problems cannot be solved on the basis of composition only, however, so that advantage can also be taken of the often heterogeneous nature of ancient glass to draw additional information from microstructure as investigated by scanning electron microscopy (SEM, cf. Chapter 2.3). As extensively determined in geochemistry since the 1950s, variations of the abundances of either stable or radiogenic isotopes represent yet other tracers of past phenomena with an unprecedented resolution whose application to glass studies will thus be illustrated. But a few words about the origins of early glass are appropriate before describing how these three methods are applied to a variety of problems.

2 Early Glass: From Faience to Glassmaking

The early objects were all small. Many, if not most, contain glass that is imperfect. Following the argument of Lucas and Harris [4], it is very tempting to see these objects as by-products of the glazing material deposited on stone and faience, two well-established products across the Mediterranean and beyond (Chapter 10.6). The powders used in glazed stone and faience is thought to have been made up of the same raw materials as the later glass. Errors in the manufacturing process could relatively easily have led to the production of small amounts of imperfect glass, which would have been worked into the occasional bead or amulet alongside the more normal faience. Peltenburg [1] saw this evolution as two clear stages of glass production: Stage 1, where the unique properties of glass were not realized yet so that glass was infrequent and irregular, and Stage 2, where glass was deliberately produced and its properties exploited. Peltenburg argued that the most significant change between the two stages was the ability to work the glass hot to create larger objects and vessels, and he has linked this feature with the only other

industry that manipulated material at high temperatures, metalworking.

However, Shortland [2] has contended that glass could, and was, manipulated cold, with stoneworking technologies, so that the important step might just have been a greater desire for glass, rather than necessarily any technological jump. The fact is that the rise of glass coincides with the beginning of the states of the Near East and Egypt regarding themselves as imperial powers. This new situation led to campaigns, conflict, and competitive gift giving on a huge scale, in which glass played a part. In this period, glass was regarded as a precious material, of equal value to lapis lazuli and turquoise, and exchanged as such. Gift lists and temple offertory scenes show glass being given and the value in which it was placed [2]. Perhaps this political reality of the new times meant that glass had a new “market” for use that drove the innovation.

Whatever the cause of the innovation, glass starts to appear in quantity in archeological contexts of the fifteenth century and by the fourteenth is widespread, but never common, in keeping with its high value. Where the first manufacturing sites for glass were located is again unclear and the former glass production sites identified remain rare. It is probable that the production of glass objects was in two stages, *glassmaking*, where glass ingots or chunks were produced from raw materials, and *glassworking*, where this glass was worked into finished objects [6]. Certainly, it has been strongly argued that in later periods these operations could, and were indeed usually taking place on separate sites some distance from each other (Chapter 10.3). The conventional argument is that the first glassmaking factories were in the Near East, probably in what is now Northern Syria [3]. It is based on some early finds of glass vessels in this area, and also on finds from the site of Nuzi, near modern Kirkuk, which had large amounts of glass connected with a destruction level evident in the temple and palace complexes and was dated to the fifteenth century BCE. Because modern scholarship now puts this destruction level in the middle of the fourteenth century BCE, it is now less clear that the Near Eastern glass predates that of Egypt. Either could have had the first glass factories.

The picture is complicated because no glassmaking sites are known from the Near East [2, 3]. The two earliest sites known are in Egypt. Malkata is on the west bank of the Nile, dates from the early years of the fourteenth century BCE, but the full excavation has never been properly published. The earliest really good evidence therefore comes from Amarna, in middle Egypt, where it is probable that glass was made and certain that it was extensively worked. Much of our knowledge of glass production in the LBA is drawn from this site and the slightly later Qantir [7, 8].

Figure 3 Inlay, Egyptian from Thebes, 18th dynasty (33 × 26 cm, British Museum EA 64217). Source: © The Trustees of the British Museum.

Although the most common objects were glass beads, amulets (Figure 2) and inlays (Figure 3) were also important. The material is almost always brightly colored, colorless glass being relatively rare but nevertheless present.

In any case, it is the glass vessels that stand out and are probably the most iconic objects of glass in the LBA (Figure 4). They are striking objects and always would have been, partly because of their beautiful color: they are typically blue bodied with trailed and marvered decoration in contrasting blues, yellow, and/or white. These objects passed down to us almost unweathered and unchanged in many of the Egyptian vessels. Most of them are small, averaging around 10–12 cm in height. Their exact use is unclear. They are found in elite contexts such as palaces, temples, and the tombs of the King and his court. They probably contained precious oils and resins and some at least were associated with toiletry boxes and make up [4].

3 Chemical Composition: The Analytical Standpoint

From a scientific standpoint, attention first turned to the chemical composition of ancient glass (cf. Table 1). Especially for Egyptian products, this interest stretches back to the eighteenth century [4]. Although some early work by wet-chemical analysis was carried out in the nineteenth century, it was not really until the middle of the twentieth that a concerted effort relied on scientific analysis to investigate composition and formation processes. The most important of this work was done by W.E.S. Turner (see Chapter 10.11), whose six published papers in the *Journal of Glass Studies* between 1954 and 1959 set the standard for further investigations, especially on the changes in chemical composition and raw materials [10].

Over the last two decades the amount of analytical work carried out on LBA glass has greatly increased. This has come about for a variety of reasons. Firstly, the development of new techniques requiring very small sample sizes such as LA-ICPMS (Chapter 5.1) has meant that the range of objects that can be analyzed has greatly increased. Secondly, new developments, particularly in the isotopic analysis of glass, have meant that new theories and possibilities could be tested. Lastly, the number of groups involved in analysis has greatly increased, bringing more papers and more interest into the area.

The key questions asked to the analytical specialist by historians and archeologists working with glass are those that Turner was trying to answer in the 1950s: How was it made? Where was it made? The work has therefore addressed the technology of glassmaking and glassworking and the provenance of individual glass vessels and ingots.

The technology of glassmaking starts with the selection and gathering of the raw materials, their transport, and storage. The manufacturing facility then needs equipping with furnaces, crucibles, tools, fuel, and staff. The molten glass then has to be molded into ingots or cooled and broken into cullet for transport. Most of the scientific work

(b)

Figure 4 (a) Egypt (cosmetic jug, 18th dynasty, 24 × 30 cm; British Museum 22819); (b) Ur, Mesopotamia (fluted glass bottle, height 11.8 cm; BM 120659). Source: (a, b): © The Trustees of the British Museum.

has concentrated on the analysis of the raw materials and the technology that was used to convert them into glass. The main analytical tool used for this work has been the scanning electron microscope (Chapter 2.3) with an attached energy-dispersive spectrometer (SEM-EDS). Thanks to its imaging (SEM) and compositional (EDS) capabilities, SEM-EDS actually is an ideal tool for the initial work on glass of all periods, but perhaps especially on early glass. Work started on polished cross sections of the glass and glassmaking debris. It has since then developed into analyses of small stub-mounted samples with environmental SEM, which even allows analysis of complete objects to be made without needing to coat them with carbon or gold.

As a nice complement to SEM-EDS, the microprobe SEM-WDXS can also be used ([11], Chapter 10.3). The SEM imaging systems on most microprobes are not optimized, or even absent altogether, so obtaining good images is better left to a proper SEM. In contrast, the analytical abilities of the microprobe, in terms of precision,

accuracy, and limits of detection, with certain limitations, are better than for an SEM. A combination of better quality SEM-EDS analyses with newer systems combined with reliable microprobe analyses of more minor and some trace elements has enabled more work on colorants to be undertaken and new hypotheses on the sources of the raw materials used for glassmaking and on their mineral or metallic nature to be formulated.

Regarding isotopic analyses aiming at provenancing of archeological artifacts, it is beyond the scope of this chapter to review the chemical principles and analytical methodology. In summary, these analytical procedures utilize well-established chemical methods of acid dissolution and ion-exchange chromatography for the isolation and purification of microgram quantities of target element from the sample. By using laser ablation, one can strongly reduce the sample consumption so that artifacts can be analyzed in a quasi-nondestructive way, a development with great prospects in archeological research, where

sampling of an object may be problematic. To exclude contamination, the chemical preparation of the material sampled is done in a clean lab environment where necessary.

4 Material Sources

4.1 Raw Materials

The EDS has the capability of analyzing most elements heavier than carbon. It can, therefore, detect more than 99% of all the elements that are present in LBA glasses. The detection limits for most elements can be around 0.1% or less in ideal circumstances. Small samples can be taken and polished blocks produced that are an excellent target for the analysis. The required sample size can be much smaller than for wet-chemistry or atomic-absorption-type techniques, and the sample is preserved so it can be imaged too.

Studies with the SEM-EDS in the early 1980s expanded on the earlier work of Turner and others to give a clear idea of the raw materials used in the earliest glass. They showed that all glass of this period is of a quite uniform soda-lime-silica composition, typically 16–21 wt % Na_2O (*soda*), 4–5% CaO (*lime*), and 58–68% SiO_2 (*silica*). In addition, significant amounts of magnesia (3–5% MgO) and potash (1.5–3.0% K_2O) are found, in stark contrast to almost all later Roman glasses where both oxides have typically much lower concentrations (Chapter 10.3).

Turner [9], supported by later SEM work by Lilyquist and Brill [5] and others, suggested that this clear pattern was caused by the use of different raw materials, specifically different silica and soda sources. Silica must have been derived from a sand, pebbles, or rock source. Pure, or nearly pure, silica sources that are needed for the production of glass have very high melting temperatures, hundreds of degrees above the 1100–1200 °C that would be the absolute maximum that an ancient furnace of this period could have reached. It was therefore necessary to add a flux to lower the temperature of melting. The differing compositions have therefore been interpreted universally as different silica source-flux combinations.

In the Roman period, a relatively pure soda flux was used in the form of sodium carbonate and related minerals from evaporitic lakes such as the Wadi Natrun in Egypt. This source was relatively low in magnesia and potash but resulted in a similar glass ([10], Chapter 10.3). In contrast, during the LBA, high-magnesia, high-potash glass is thought to have derived from the ash produced by the burning of halophytic plants, such as *Salsola* and *Salicornia*, which grow on the margins of deserts and in coastal areas. Interestingly, there is a third type of glass with low

magnesia and high potash values, sometimes known as “LMHK” [12], which has almost equal amounts of soda and potash. This glass type was restricted to the Bronze Age of Europe and overlapped temporally with the LBA glass of Egypt, Greece, and the Near East discussed here. Once again it appears to have used a different flux source, but in this case, this source has never been universally agreed.

4.2 Coloring Elements

Because most of the glass of this period is strongly colored, SEM-EDS has been valuable to identify the elements used for this purpose. A simple procedure consists in identifying the elements that are present in excess in colored materials with respect to colorless glass (cf. Chapter 6.2). Blue is the most common hue, which is generally caused by copper. Darker blues were achieved with cobalt, and occasionally with a mixture of cobalt and copper. White glasses have higher levels of antimony, and yellow glasses of both lead and antimony, which points to the presence of antimonate opacifiers. Opaque blue glasses colored with copper and/or cobalt may also have higher antimony, which suggests that they too had an opacifier. Green glasses contain copper, lead, and antimony, which indicates either a mixing of yellow and copper blue glasses, or the combination of the technology used in the production of each. Purple and black glasses had small and large amounts of added manganese, respectively, whereas red once more relied primarily on higher copper contents. Work on the composition of LBA glass has proven very valuable and has been supplemented by further systematic analysis with microprobe SEM-WDXS.

Instead of asking what the coloring element of a blue glass might have been – copper, as is well known for a majority of glasses – the question has moved to know how this element was added to the glass: was it as malachite $[\text{Cu}_2\text{CO}_3(\text{OH})_2]$, copper oxide, copper metal or bronze, scrap or pristine metal? For copper, it has been observed that some glasses contain traces of tin, as first noted with copper-blue faience. This feature seems to have been a characteristic of most, but not all, copper-blue glasses found in Egypt. The copper:tin ratio in the glass is about 10 : 1, roughly the same as in contemporary bronze metal, so it is possible that the colorant added to Egyptian glasses was bronze filings, scale, or metal. In contrast, tin is absent in glasses found in the Near East, so a copper metal or ore is more likely.

4.3 Opacifying Agents

Highly magnified images of glasses taken with the SEM have greatly added to the knowledge of glass colorants.

Imaging of the copper red glasses has, for instance, shown fine dendritic growths of cuprite (Cu_2O), giving the material its distinct color (Chapter 6.2). As for the aforementioned opacity in many glasses, it is caused by the presence of crystalline particles. White and opaque blue glasses are created by the presence of a fairly uniform spread of calcium antimonate whose morphology likely shows that they precipitated out of the glass itself. According to XRD analyses, the phase present is variable and complex and may relate to both the composition and cooling regime of the glass, which might have varied from a site or an area to another. Yellow and green glasses bear lead antimonate particles whose uneven distribution, along with their ragged and partially dissolved appearance, suggest that they formed first before being dispersed by stirring into the glass rather than precipitating out of it. These conclusions have been confirmed by experimental work that has shown that the calcium antimonate precipitates out of the glass in white and opaque blue colors, whereas the lead antimonate must be added and stirred in.

4.4 Frit or Not?

Besides, SEM imaging has been extensively used in attempts to identify and describe workshop debris, tools, and even intermediate steps in glassmaking. Excavations at Amarna in Middle Egypt in the later nineteenth and early twentieth centuries along with more modern excavations at Qantir [7, 8] have, for example, unearthed a range of debris that might have been involved in glassmaking. Early work by Petrie [13], followed up by analysis, suggested that the raw materials for glassmaking had been heated to drive off volatiles, or *fritted*, before being finally crushed and melted. Petrie identified vessels containing a blue vitrified quartz held together with glass, which he identified as *frit* remaining from this process. Work by SEM imaging combined with EDS showed that the composition was wrong, however, so that glass could not have been made from this *frit* without substantial additions of flux, which would have negated the point of the fritting in the first place. Hence, it is clear that this material was more likely involved in faience or pigment manufacture. Recent work on Amarna material has identified a frothy white opaque glass that may be a much better candidate as an intermediate stage in glass production.

4.5 Glass Working

Much of the analytical research has been accompanied by a good deal of experimental work of two different types: either detailed replication of usually single steps in the glassmaking process with modern kilns and mostly laboratory reagents, or experimental firings in the field

attempting to replicate the operation of ancient furnaces and other structures.

Whole furnaces have, for instance, been built in Egypt, along the lines of the ancient ones discovered at Amarna [7]. Doubt had been expressed that these quite large furnaces could not reach glassmaking conditions, but experimental work has shown that their design actually made temperatures in excess of 1000 °C possible. Of course, this conclusion does not mean that these furnaces were used in the manufacture of glass, but does dispel the doubt that in terms of temperature at least, they were capable of it.

Imaging by SEM of the vessels and furnaces that might have been used in glassmaking has in addition been carried out. The question asked here was that of the temperature at which furnaces were being fired. To answer it, the microstructure of cross sections of the furnace and vessels walls has been investigated by SEM and the observed fabrics compared with experimentally refired samples of clay from the same site. The closest match was then taken as indicative of temperatures of 1050–1100 °C.

The final products of *glassmaking* in this period were probably circular glass ingots. While rare in terrestrial excavations, a remarkably high number of 175 ingots were recovered from the LBA ship found at Uluburun, off the southern Turkish coast. These ingots were probably the normal form in which glass traveled, to be worked into finished objects at other sites.

Analysis of glass vessels by SEM has shown how this glassworking might have been carried out. The internal surfaces of the glass vessels are usually covered with the remains of a core, which was subsequently scraped out. With these core-forming techniques, a core of clay and/or dung was dipped into the molten glass to form the body of the vessel. One then decorated the vessel by trailing glass rods across the surface and marvering them flat. The trailed decoration forms a characteristic semicircular shape, which can clearly be seen in cross sections through the wall of the glass vessel examined under SEM.

5 The Issue of Provenance

The principal requirement of provenancing glass of any period is that there should be consistent variation in the composition of the finished glass between different primary glass manufacturing workshops. In some periods, this is relatively easy to see since the different fluxes used in different areas gave rise to markedly different compositions [10]. Unfortunately, however, the flux is all plant ash in the LBA of the area discussed here. Not only that, but within certain criteria, the composition of

the glass forms quite a wide spread, perhaps caused by variability in the raw materials and/or furnace conditions. In terms of major elements and most colorants, therefore, the glass looks very similar regardless of where it was found or made [14].

Regarding the identification of pigment sources in these early glasses, a breakthrough came in the 1980s when Kaczmarczyk [15] published an important paper on cobalt, a very strong coloring agent as only 0.1% CoO makes a glass distinctively blue (Chapter 6.2). Cobalt was introduced as a coloring agent in the LBA to be used in glass, faience, and as a pigment on ceramic vessels. Pointing out that cobalt-colored glasses were common in Egypt, but rare in the Near East, Kaczmarczyk hypothesized that the source of the cobalt colorant might therefore lie in Egypt. Not only that, but trace-element analysis by SEM-EDS of Co-colored glasses showed that where cobalt was present, the aluminum, manganese, nickel, and zinc levels of the glasses were also raised, suggesting that the cobalt colorant contained these other elements as well. Because cobalt minerals are rare, and native cobalt unknown, possible sources are relatively few so that Kaczmarczyk pointed to cobalt-bearing alums found in the Western Oases of Egypt as the source for the colorant. Experimental work has actually shown that they produce a good cobalt-colored glass. These glasses were thus made from an Egyptian pigment and largely restricted to Egypt (except some found in Greece, by [16], and other rare exceptions). But more recent work [17] has found other Co-colored glasses at Nippur, in the Near East, in which cobalt is associated with nickel, arsenic, and lead. This difference thus points to the existence of a second, unknown cobalt source.

Unfortunately, this approach has only really worked for cobalt colorants. For other colors, it has proved very difficult to differentiate production sites. Indeed, Jackson [14] said “glass from Egypt and Mesopotamia cannot be unequivocally distinguished on the basis of their chemistry.” This statement was demonstrated by a large survey of the glass by SEM-WDS. What was needed was a technique with lower detection limits, where not just 12–14 elements in the glass could be analyzed, but 35–40. The step forward came with the application of LA-ICPMS to the analyses of these glasses. The argument used in this analysis was that the composition of the glass should reflect that of the plant ash being used. It in turn would reflect the composition of the plant itself, which might vary depending on the soil in which it grew, itself dependent on the geology. The composition of the glass might therefore reflect the geology of the region in which it was made.

With this theoretical underpinning, accurate trace-element analysis of these glasses was carried out on the polished samples mounted in SEM blocks that had been

Figure 5 The clear distinction between glasses found (and therefore thought to be made) in Egypt (Amarna and Malkata) and in the Near East (Nuzi and Tell Brak) revealed by plots of ICPMS data for lanthanum against chromium.

used for earlier studies of the major element composition of the glasses. These made ideal sample mounts for LA-ICPMS, and allowed analyses to be performed down to sub-ppm levels for many elements. The results showed a consistent difference between glasses found in the Near East and in Egypt, the former having higher Cr/La and lower Zr/Ti ratios and the latter the opposite (Figure 5). It was speculated that this contrast would relate to the sources of clay in the areas – Egyptian Nile silts coming from granitic sources, whereas the clays of the great rivers of Iraq from more mafic (basaltic) sources.

Other papers have pointed out that the signature could be down to grinding debris incorporated in the glass when hard rock pounders of differing compositions were used in the grinding of the raw materials for the glass. Whatever the source, the pattern is consistent and has been seen in other glass of the same period from Greece and from the shipwreck at Ulu Burun, allowing these glasses to be provenanced to the Near East and/or Egypt.

6 The Isotopic Clues

6.1 Isotopic Analyses

More and more, the question “where glass was made?” is being addressed with isotopic analysis [18]. Even though the isotopic composition of the elements is assumed to be constant in nature, small variations do occur through several processes. For certain elements (e.g. Sr, Nd, Pb) the reason is that one or more of their isotopes is the end product of the decay of naturally occurring long-lived

radionuclides. Because they vary with time and the initial mother/daughter ratio, the isotopic composition of these elements are not used only for geochronological dating, but also to trace the sources of detrital matter in the sedimentary and biogeochemical cycles. Likewise, stable light elements (e.g. B, O) and even some heavier elements (Sb, Cu) display natural variations in their isotopic composition as a consequence of kinetic and thermodynamic isotope fractionation effects. Although these variations are often very small, they also reflect different origins and formation processes for raw materials.

Now, the important point in provenancing and/or source-tracing studies is that isotopic ratios in glasses depend only on those of the raw materials, and not on glassmaking processes, especially when the relative mass differences between the isotopes of the same element are small. In other words, the isotopic composition of the artifact is identical, within analytical errors, to that of the raw material from which it was derived, whereas the signatures of different raw materials used, and hence of the resulting artifacts, may differ.

6.2 Lead

Lead isotopes were the first (radiogenic) isotopes used to investigate ancient materials. Since the 1960s, they have, for instance, been extensively used in archaeometry to trace the provenance of metals, mainly from the Mediterranean Bronze Age period, even though their disadvantages have given rise to some controversy [19]. From the beginning, lead isotopes have also been analyzed in a range of archeological materials to distinguish between vitreous materials of different regions. Overlap was noted between “fields of origin,” however, as is not unusual with lead isotopes. In further studies, lead isotopes were used with varying success to link raw-material mixtures or regional signatures to glass production units. Low lead concentrations in glass, in the 10–100 ppm range, are likely to originate from non-quartz mineral constituents in the silica source, though low levels of lead have also been ascribed to impurities in plant ashes used as a flux. The discovery of a homogenous lead isotopic composition in a range of glass samples suggests that a homogenous silica raw material had been used, and perhaps that produced was made at a single location. Heterogeneous lead isotopic compositions of samples, particularly with high lead contents, are an indication of recycling of the glass or may be caused by the addition of a mineral compound to the batch as a colorant or opacifier, likely influencing or obscuring the original signal of the silica raw material. Opaque glass, in particular, could be studied to trace the origin of its lead, but such studies have not been performed yet.

6.3 Strontium–Neodymium

The application of strontium isotope analysis to ancient glass is based on the assumption that this element was incorporated with the lime-bearing constituents. Hence, strontium in LBA glass is principally derived from the plant ash used, the $^{87}\text{Sr}/^{86}\text{Sr}$ isotope ratio having thus reflected the bioavailable strontium of the soil on which these plants grew, which in turn reflected the geological origin of the soil. Plant-ash glasses can have high strontium contents, which often show considerable variations, indicative of the varied or complex source of the element and the concentrating effect of ashing the plant. This feature illustrates how important it is to establish variations in Sr isotopic signatures in the landscape as part of trying to provide a provenance for plant-ash glasses. Conversely, the neodymium in glass is likely to have originated from impurities of the silica raw material. It is thus typical of the geological environment from which the silica originated. Correlations between Sr and Nd isotope ratios should thus allow the sources of both silica and flux to be distinguished.

This method has been successfully applied to Bronze Age glass from Egypt and Mesopotamia [20, 21], where multiple production locations were proven, each having used its own set of glassmaking raw materials. Even though glass was exchanged from one LBA Mesopotamian site to another, this production was entirely separated from the making of glass in Egypt (Figure 6). Glasses of this period identified as having been traded are indeed exceptional and are analytically proven only in rare cases [16] despite textual and archeological

Figure 6 The higher resolution of isotopic analyses: distinguishing glass made in Egypt and in three other places in Mesopotamia from Sr and Nd isotopes of Late Bronze-Age samples [22]. Neodymium isotope ratio of the glass (gl) expressed as $\epsilon_{\text{Nd}} = 10^4 \left[\left(\frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right)_{\text{gl}} / \left(\frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right)_{\text{ref}} - 1 \right]$ with respect to that of a geochemical reference.

evidence that exchange did take place, e.g. the materials found in the Uluburun shipwreck in the Aegean, East of Rhodes.

6.4 Antimony

Antimony was used as an opacifier in Late Bronze to Iron Age glass. It has been suggested that it was added to the glass batch in the form of an ore (e.g. stibnite, Sb_2S_3) or possibly in its native, metallic form. Despite the fact that many analytical studies have been devoted to antimony as a raw material for colorless glass, compositional analysis had not been able to reveal the provenance of the actual minerals used. Determinations of Sb isotope ratios of ancient glass provide a new means of looking at this source. A first database of possible stibnite ore sources has thus been developed [22]. The Sb isotopic composition of LBA glass does not show a significant difference between Mesopotamian and Egyptian glass, which suggests that all factories in both Mesopotamia and Egypt used similar (or identical) sources. As this antimony has an isotopic composition that significantly differs from that of any stibnite source known from the Mediterranean area, the Near East or eastern Europe, its source is unlikely to be situated there. Likewise, LBA glass is also significantly different in Sb isotopic composition from Roman to early Byzantine glass, for which several Sb sources (as stibnite) seem to have been used and extensive recycling was common.

Although further possible sources in Iran remain unexplored, the only likely origin of the antimony used as the opacifier in ancient glassmaking throughout the Near East lies in the Caucasus where antimony metallurgy developed and native antimony and antimony-rich minerals were specifically mined. Hence, while Sr–Nd isotopic analysis clearly separates glass production in Mesopotamia and Egypt, each region using its own silica and flux sources, the opacifier tells a different story: Sb was used to opacify glass, and factories in Mesopotamia and Egypt seem to have used the same Caucasian source of the material, from the region where also Sb metallurgy first developed. In this way, a link between the development of the metal and glass industries can be shown and exchange or trade in antimony be suggested over long distances.

6.5 Copper and Boron

Because lead is one of the major impurities present in copper, its isotopes are used to distinguish different metal sources, in particular ancient copper alloys (cf. *supra*). However, significant overlap may exist between different ore fields and areas of origin. The application of isotopic analysis of Cu in archaeometry to distinguish different

groups of artifacts and metal sources offers new perspectives, especially in combination with that of Pb. Differences in the Cu isotopic composition between sulphidic and oxidized ore deposits have been reported. They could serve to distinguish the type of ore used in ancient technology, but application to provenancing glass has remained of little use so far [22].

Next to silica as a raw material for glass production, a flux is used to lower the melting temperature of pure quartz. The B isotopic composition of evaporites (like natron) has been used successfully in geological studies to distinguish different environments, and has been used to compare ancient natron flux and glass. Although plant ash glass also contains B in a content an order of magnitude higher than natron glass, this isotopic system has not been explored in provenancing this glass type [23].

7 Perspectives

With the specific information provided especially by elemental and isotopic analyses, archeologists may understand the origin (in some cases, the nature) of the raw materials used in artifact production and can begin to contribute to understand better past trade, (socio-)economic manufacturing conditions, and eventually the ancient economy. Ideally, the interpretation should combine the results with evidence from archeological excavations, historical sources, and typo-chronological study. The main issue in these archeological studies is the fact that the access to analytical facilities may be restricted and/or expensive, especially for isotopic work. More laboratories and research groups investigating isotopes in artifacts should be established, to allow for a broad base of research, enough input of new materials, and new applications of different isotope systems, and in particular new ideas and interlaboratory comparison. In particular, a synergy with the disciplines of chemistry and earth sciences would be effective in this respect, and would facilitate further work in the analysis of ancient glass.

10.3

Roman Glass

Ian C. Freestone

Institute of Archaeology, University College London, London, UK

1 Introduction

Although the first man-made glass vessels emerge in the archeological record in the sixteenth century BCE (Chapter 10.2), for the next 1500 years glass remained a rare and difficult-to-access material, typically opaque and strongly colored. For much of this time, glass was seen as an artificial stone and its use was restricted to the elites of societies in western Asia and the eastern Mediterranean [1]. In the first century BCE, however, a revolution occurred. Technological developments, notably the recognition that hot glass could be inflated with an iron blowpipe, and the melting of raw materials on a scale of tonnes, allowed an expansion of production to supply the demands of the Roman Empire. At its maximum extent, this Empire stretched from Syria to the Atlantic, and Roman glass has been found in archeological contexts as far afield as Japan and Norway.

Scale and technical prowess are two of the defining characteristics of the Roman glass industry. In terms of scale, it has been estimated that a single large public building, the Baths of Caracalla in Rome, required of the order of 300 tonnes of glass window pane and wall mosaic in its construction [2]. In terms of technological achievements, Roman glass was more-or-less equivalent to that of an eighteenth-century European industry, with sophisticated but empirically based methods of manipulating color and form.

In this chapter, I consider the “long” Roman glass industry, where the making of glass raw material was centered on the south-eastern Mediterranean, and based upon the use of naturally occurring sodium minerals and quartz-calcite sand. This tradition of making was

established around the middle centuries of the first millennium BCE and did not finish until around 800 CE, by which time the major centers of glassmaking were no longer Roman but part of Islamic societies. The glass material itself still kept a distinctively Roman character, however.

2 Glass Synthesis

2.1 The Importance of Natron

The only detailed contemporary account of Roman glassmaking is provided by the *Historia Naturalis* of Pliny the Elder, written in about 70 CE. Pliny's account is in many respects vague and open to interpretation but, along with reports of other classical authors such as Strabo (–64 to +25) and Flavius Josephus (30 to ~100), it is clear that it mentions glass made from sand was found close to the mouth of the River Belus (modern R. Na'aman), in the Bay of Haifa. Modern analyses of eastern Mediterranean coastal sand between the Nile and southern Lebanon indicate that it mainly comprises quartz with subordinate shell (CaCO_3) and minor feldspar. With the addition of appropriate amounts of soda, the sands around Haifa would yield a soda-lime-silica glass with a typical Roman composition, containing around 3 wt % Al_2O_3 and 8 wt % CaO (Table 1). Compared with other sands of the coast of Israel, those from the Bay of Haifa have a low color index, implying a relatively low iron content, so that they were likely among the best on the eastern Mediterranean coast for the manufacture of glass. Pliny is also clear that the preferred glassmaking flux was Egyptian *nitrum*, identified as evaporitic salts precipitated from soda lakes in the Wadi Natrun, some 50 km northwest of modern Cairo and from a number of other lakes in the Delta region [3].

Table 1 Example compositions of natron-based transparent glass of various Roman compositional types.

	Roman-Sb	Roman-Mn	HIMT	Egypt I	Levantine
Century	1st–3rd	1st–3rd	4th–5th	7th	8th
SiO ₂	69.00	69.83	64.49	71.36	73.76
Na ₂ O	19.06	16.05	19.07	17.02	12.10
CaO	6.23	7.72	6.22	3.04	7.42
Al ₂ O ₃	1.71	2.24	2.88	4.20	3.58
K ₂ O	0.39	0.62	0.41	0.53	0.45
MgO	0.40	0.54	1.23	0.81	0.69
Fe ₂ O ₃	0.41	0.42	2.28	1.55	0.61
TiO ₂	0.06	0.07	0.49	0.47	0.12
MnO	0.02	1.14	2.02	0.05	0.02
Sb ₂ O ₅	1.03	—	—	—	—

“HIMT” is a type with particularly “high iron titanium and manganese.”

The most reactive flux in the Wadi Natrun assemblage is the sodium carbonate mineral *trona* [Na₂(CO₃) · NaH(CO₃) · 2H₂O], but mixed salts, sulphates, and chlorides are also abundant. These are collectively termed “natron” by archeologists, although this is strictly incorrect, not only because mineralogically defined natron actually is Na₂CO₃ · 10H₂O, but also because the extent to which the trona was deliberately selected or purified for glass-making is not fully understood. However, it is clear from nineteenth and twentieth-century experience with the manufacture of *saltcake* (sodium sulphate) glass that the presence of minor amounts of charcoal in the batch, inevitable in the wood-fired installations used by the Romans, would have decomposed sodium sulphates to the more reactive sulphites and promoted melting. Unreacted salts would have then separated as an immiscible scum or gall, which could be skimmed from the surface of the molten glass, as actually indicated by the fact that virtually all Roman glass contains of the order of 1 wt % chlorine, which is around its solubility limit in soda-lime-silica melt at high temperature, along with minor amounts of sulphate.

In the widely accepted sand-plus-natron model for glass manufacture, lime [CaO] is generally considered as an incidental component in the sand rather than as an intentional additive to the glass batch. Whereas this is the generally held view, it may not necessarily have always been the case so that some authors consider that lime was added deliberately instead. Pliny himself indicated that shell was added to glass, which might have indicated an attempt to balance the composition by addition of lime. The obvious problem here is that it is difficult to distinguish by compositional analysis intentionally added crushed shell from a shelly component of beach sand.

The relatively pure character of Egyptian natron and the low amounts of accessory minerals in the glassmaking sands yielded glasses with relatively low amounts of potassium and magnesium oxides, typically around 0.5% each. These *low-magnesia* soda-lime-silica glasses are clearly identifiable in the archeological record. Plant ashes, with significantly higher concentrations of MgO and K₂O, were the favored source of flux for most other glassmaking traditions from the Bronze Age through to the Renaissance. Because they gave rise to glasses having typically an excess of 2% each of these components, natron glass is very distinctive. Examples of a range of colorless and transparent glasses are presented in Table 1, where Al₂O₃ in the range 2–3 wt % is characteristic, whereas Fe₂O₃ is invariably present at 0.3 wt % or greater, an order of magnitude higher than the specification for modern colorless glass.

2.2 Melting Furnaces

The sheer size of Roman glass production has raised the question of how the melting process was conducted. Because archeological evidence for large-scale furnaces was lacking, it was commonly assumed that glass was made in the workshops where vessels were shaped. In the 1960s, however, a large slab of failed glass, weighing 8 tonnes and measuring c. 3.4 × 2 × 0.5 m was first reported by Robert Brill from a cave in the Byzantine necropolis at Beth Shearim, Israel. This slab contained excess CaO (16 wt %), which led it to devitrify on cooling to calcium silicate, which presumably led to its abandonment by the glassmakers. For many years it was considered something of an oddity, but in 1992, in Beth Eli'ezer, a location near Hadera, archeologists of the Israel Antiquities Authority reported an array of 17 furnace floors of tank furnaces, each of which would have melted a slab of glass equivalent in size to that at Beth Shearim (Figure 1) [4]. The Beth Eli'ezer furnaces are early Islamic (eighth century) but the products are of Roman-type composition.

More recently, the remains of more Roman tank furnaces, which would have contained between 8 and 20 tonnes of glass, have been excavated in the coastal strip of modern Israel, and in Egypt, close to the sources of good-quality sand and of natron [5]. These rectangular furnaces operated on the reverberatory principle whereby heat from fire boxes at one end of the tank was reflected from an arched roof down onto the surface of the glass. The raw materials were added in layers to facilitate melting, which took place over weeks or more at temperatures that were not especially high relative to those of pottery kilns of the period, probably around 1100 °C [5].

Our understanding of the details of the process and the operation of the furnaces is in need of refinement, but has

Figure 1 Array of excavated floors of tank furnaces at Bet Eli'ezer, near Hadera, Israel. Each furnace is thought to have melted sand and natron to make around 8 tonnes of glass. *Source:* Photo Jochai Rosen, courtesy Israel Antiquities Authority.

been greatly informed by ethnographic investigation of a recently active furnace in India, which melted a slab of around 3 tonnes of glass in a firing that lasted for 30 days [6]. Detailed information on the fuels used is not presently available, but it is assumed that, in the Levant and North Africa, where timber resources were limited, the by-products of agricultural industries producing commodities such as sugar and olive oil would have been used. There appears to be no evidence for the use of charcoal as a fuel. Actually, charcoal would not have been necessary to achieve the required temperatures but, more importantly, the reducing atmospheres generated by this fuel would have produced strong iron-related discoloration of the glasses, which contained over 0.3% Fe_2O_3 , and in some cases up to 3%.

3 Provenance and Location of Glassmaking

The recognition that glass was made as a bulk material in large installations close to the sources of sand and alkali in

the eastern Mediterranean has revolutionized our understanding of Roman glass and of its composition. It is now clear that glass was transported in the form of raw chunks from the *primary* glassmaking facilities to workshops across the Empire where it was fabricated into vessels. There is abundant evidence for the long-distance transport of raw glass in the form of angular chunks or lumps, which have been found in shipwrecks, such as that west of the island of Les Embiez, off Cannes, in the Mediterranean. The raw glass was remelted and shaped in *secondary* workshops into vessels, windows, and small decorative items such as beads, bangles, and amulets for local or regional consumption. This current understanding is summarized in Figure 2.

This model of production division means that the use of chemical compositions to attribute glass vessels to the workshops where they were formed is a challenging endeavor. Considerable attention has nonetheless been paid to the categorization of glass into compositional groups related to the locations of primary production because deciphering the trade of raw glass represents a tool to help understand the ancient economy.

Figure 2 Model for Roman glass production as currently understood. Egyptian soda was transported to primary production centers in Egypt and on the Levantine coast where it was mixed with local sand and melted into glass. The raw glass was transported to numerous workshops around the Empire to be remelted for the production of vessels and windows.

As Roman glass was made from sand and natron, the latter being a relatively pure mixture of sodium salts, the characterization of a glass source essentially reduces to a matter of sand geochemistry. Roman glassmaking sand can be considered to have comprised four constituents: quartz, limestone/shell, feldspar, and heavy minerals. The initial identification of primary production groups has mainly focused upon major and minor elements, where SiO_2 is a proxy for quartz, Al_2O_3 for feldspar and clays, CaO for shell/limestone, and Fe_2O_3 for heavy minerals. Data for these constituents are widely available through major-element analyses performed by different laboratories, which are generally sufficiently compatible to demonstrate relatively subtle differences between the groups (Table 1). It has, for instance, become clear that TiO_2 content is a very effective discriminant between Egyptian and Levantine glass sources, thanks to which it is possible to recognize around nine major groups (Figure 3).

Recently, more detailed information has been drawn from isotopic analyses because variations of the ratios between the abundances of radiogenic and non-radiogenic isotopes may represent a tracer of the source of a given chemical element. In this respect, strontium is especially useful for deciphering the origin of lime

because, as an alkaline earth element, it closely follows Ca in geochemical cycles and, in particular, in the carbonate precipitation of animal shells. Now, ^{87}Sr is the only radiogenic isotope of strontium, forming by radioactive decay of ^{87}Rb , so that the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of rocks and minerals increase with their geological age as well as with their Rb content. In sea water, strontium originates from the weathering of all types of rocks. Its $^{87}\text{Sr}/^{86}\text{Sr}$ value has also increased through time, being dominated in a relatively recent geological past by the erosion of the Himalayas to reach a characteristically high value of 0.7092. Assuming that most of the Sr in glass is derived from the CaCO_3 component in the batch, one discriminates between beach shell (with the $^{87}\text{Sr}/^{86}\text{Sr}$ value close to 0.7092) and other sources of lime that may have higher or lower values. Among several hundred glasses of the first millennium CE, the overwhelming majority was thus made from shell rather than from limestone, having $^{87}\text{Sr}/^{86}\text{Sr}$ values in the range of 0.7087–0.7092 [10]. This conclusion thus is concordant with the account of Pliny and other classical authors on the use of beach sand to manufacture glass, only the chronologically latest-occurring group shown in Figure 3 (Egypt II, dating eighth to ninth centuries) having been made from inland sand ($^{87}\text{Sr}/^{86}\text{Sr}$ values: 0.7079–0.7081) [10].

Insights into the origin of sand can also be gained from isotopic analyses, but in a somewhat more complicated way through variations of $^{143}\text{Nd}/^{144}\text{Nd}$ ratios. Like the other lanthanides, neodymium is a rare earth primarily present in the heavy-mineral fraction of a sand (Chapter 1.2). Because ^{143}Nd forms by the radioactive decay of ^{147}Sm , the bulk $^{143}\text{Nd}/^{144}\text{Nd}$ of a sand therefore reflects the age of the source rocks that weathered to produce it. In practice, $^{143}\text{Nd}/^{144}\text{Nd}$ is frequently expressed relative to the primordial isotopic composition of the solar system to give a parameter $\mathcal{E}_{\text{Nd}}$, which is largely positive for young volcanic rocks and strongly negative for older crystalline rocks. This relationship is very useful in investigations of Roman glass production because the beach sands of the eastern Mediterranean carry heavy minerals predominantly deposited by the Nile, which were derived from the young volcanic rocks of East Africa.

The $^{143}\text{Nd}/^{144}\text{Nd}$ of a glass can therefore act as a fingerprint for the region of origin of the sand. A survey of the beach sands of the western Mediterranean reveals $\mathcal{E}_{\text{Nd}}$ typically much more negative (typical values –8 to –12) than for the coasts of Palestine and Egypt (typical values –1 to –6). The majority of Roman to early Islamic glass, including that from primary production furnaces on the Levantine coast, has $\mathcal{E}_{\text{Nd}}$ values in the range –3 to –7, consistent with production in the eastern Mediterranean as opposed to the western Mediterranean, where $\mathcal{E}_{\text{Nd}}$ would be significantly lower [10]. Hence, most authors now agree that the majority of natron glass

Figure 3 Main compositional groups of the first millennium CE as determined from differences in major-element contents. Source: Data from [7–9].

was made in the regions of modern Egypt, Israel, and possibly Lebanon.

If neodymium isotopes provide a useful tool to determine the general region of origin of a glass, they are less effective for the determination of a precise origin. The determination of minor and trace elements made possible by the adoption of laser ablation mass spectrometric methods is proving effective in this area. For example, a glass in the natron tradition characterized by high trace contents of boron and lithium has recently been demonstrated to originate from western Anatolia where there are extensive borate deposits [11].

To summarize, it currently appears that most Roman glass was made from sand and mineral alkali in the eastern Mediterranean. Whereas Pliny suggested that glass was produced from its raw materials in Italy, Gaul, and Spain, the isotopic evidence suggests that any production that occurred in these regions was likely minor. Production of a small proportion of glass further West has been suggested from the data [10], but the locations of these productions are not clear.

4 Color Generation and Control

4.1 Transparent Glass

Roman transparent glass of the first to third centuries CE typically contains around 0.4 wt % Fe_xO_y . As revealed by X-ray absorption spectroscopy analyses (Chapter 2.2) of glass vessels and material from production sites [12], around half of this iron is Fe^{2+} whose strong absorption in the red part of the spectrum imparts a distinct green-blue hue to typical transparent glass from primary furnaces (Chapter 6.2). However, a frequent practice was to add manganese dioxide [pyrolusite, MnO_2] or

antimony oxide [Sb_2O_5] to the glass to oxidize the iron and minimize this blue color. Glasses decolorized in this way have over 90% of their iron as Fe^{3+} and are virtually colorless in vessels with walls a few mm thick [12]. Glass decolorized with antimony had the least tint and, as concluded from the limited available data, a higher $\text{Fe}^{3+}/\Sigma\text{Fe}$, presumably because of the relative potential of the $\text{Sb}^{3+} - \text{Sb}^{5+}$ redox couple (Chapter 5.6). The decolorizers were often added to the batch at the primary/raw glassmaking stage, as, for example, indicated by the composition of glasses from the furnaces of the Wadi Natrun.

According to Pliny, colorless glass resembling rock crystal was the most valued type in the later first century CE, which appears to have also been the case around 300 CE, when the Edict of Maximum Prices by the emperor Diocletian (r. 284–350) specified the cost of green-blue glass to be about two-thirds that of colorless glass [13]. Limpid greenish-blue glass is the most common type encountered, whereas Sb-decolorized glass was more frequently used for high-quality vessels than Mn-decolorized glass, for example, those with cut decoration where optical quality was most important. It may be that the effectiveness of Sb as a refining agent was also a contributor to the value attached to this type of glass.

From the fourth century, marked changes occurred in the glass industry. New production centers used sand that often contained in excess of 1% Fe_2O_3 so that the quality of much of the glass declined. Whereas the intensity of the color appears to have been reduced by MnO_2 addition, the higher total iron typically resulted in a yellowish green tint even when the bulk of the iron was oxidized. In some compositional groups, there is a general correlation between iron and manganese contents, which appears to indicate a systematic approach to control color; similar correlations are not seen again until Renaissance Venice (Chapter 10.7).

4.2 Colored and Opaque Glass

For production of colored glass, the Roman technologies were closely similar to those used since the second millennium BCE. For translucent glass, the color was determined by a limited range of elements – Co^{2+} (deep blue); Cu^{2+} to give turquoise, or modified by lead or iron to give green; Mn^{3+} to give purple. Amber, due to the ferri-sulphide chromophore (S^{2-} – Fe^{3+} charge transfer, see Chapter 6.2), was formed under exceptionally reducing conditions in the primary glassmaking furnaces. Copper is typically associated with minor amounts of tin, lead, or zinc and is therefore believed to have been added in the form of the oxide scale formed upon heating of scrap bronze; the locations of the ores that provided the cobalt and manganese are not yet identified.

Opaque and strongly colored glass was also routinely made with a variety of appropriate compounds [14] (Figure 4, Table 2). High-quality opaque white glass, for instance, resulted from precipitation of calcium

Figure 4 The Lycurgus Cup (fourth c. CE) depicting the myth of King Lycurgus in cut openwork. The cup is colored by Ag–Au–Cu nanoparticles and appears red in transmission and green in reflection. It was cut from a thick-walled blown blank. The metal base and rim were added in early modern times. Height: 16.5 cm (with metal mounts). CoO	0.25	—	—	—	—	—
Crystals	Ca–Sb	Ca–Sb	Pb–Sb	Pb–Sb	Cu	Cu_2O

antimonates [$\text{Ca}_2\text{Sb}_2\text{O}_7$ and CaSb_2O_6] upon addition of antimony. In combination with Co^{2+} and Cu^{2+} dissolved in the glass matrix, these antimonates could alternatively produce deep opaque blue and turquoise, respectively. Another ingredient was lead antimonate [$\text{Pb}_2\text{Sb}_2\text{O}_7$]. It was preformed as a pigment before mixing with the soda-lime-silica glass in which its distribution was less homogeneous. It was relatively unstable at high temperature but yielded opaque yellows and greens along with dissolved Cu^{2+} . As for opaque reds, they were produced by the precipitation of metallic copper particles of the order of several hundred micrometers diameter. The reduction of the dissolved copper oxide into metal according to the reaction

was achieved by addition to the molten glass of either iron or of carbon in the form of furnace ash. Another type of red glass was produced by the precipitation of dendritic cuprous oxide [Cu_2O , cuprite] in a lead-rich soda-lime-silica glass matrix; a purer *sealing wax red* was in general obtained than with metallic particles, which yielded a more red-brown hue (Table 2).

As a translucent material, red glass was extremely rare before the modern period but a small group of vessels dating to the fourth century owe this color to metallic alloy nanoparticles (Chapter 6.2). The most famous is the Lycurgus Cup of the British Museum (Figure 4), which contains 30 wt % Au, 60% Ag, and 10% Cu [15]. Because the cup appears red in transmission and green in reflection, the suggestion has been made that it symbolizes the

ripening of the grape. How gold was dissolved in the glass by the Romans is uncertain, but it is usually accompanied by silver and copper in very variable amounts, perhaps pointing to a poorly controlled reaction between hot glass and molten metal such that the most easily oxidized constituents of a gold alloy (Ag and Cu) were dissolved disproportionately.

Recent work on pink or flesh-colored tesserae from mosaics, again mainly dated to the fourth century, indicates that they owe their color to a combination of gold nanoparticles and calcium antimonate [16]. It therefore seems that gold coloration was a deliberate technology adopted by the Romans at this time. Significant amounts of tin are not present in these glasses. It appears that the reduction of Au^+ to Au^0 was achieved instead by the donation of an electron from Sb^{3+} or Fe^{2+} .

At some time in the fourth century, the use of antimony as a glass additive appears to have ceased or greatly diminished. Since Sb-decolorized glass was no longer made, the occurrence of antimony-opacified glass in some enamels and mosaics may be explained in terms of recycling or reuse of old colored glass. Whereas manganese became the only decolorizer used, opacification was achieved largely with compounds of tin, specifically SnO_2 (white) or $\text{Pb}_2\text{Sn}_2\text{O}_6$ (yellow). Presumably because tin then became either inaccessible or too expensive, by the tenth century, crushed quartz was widely used to opacify the tesserae of Byzantine mosaics.

A currently unsolved problem is that of the places where glass was opacified and colored. Colored and opaque glass was much less common than weakly tinted glass, more costly to produce, and used particularly in elite houses and institutions, for example in wall mosaics. Furthermore, archeological finds of certain strongly colored glass such as cameo vessels are concentrated in or around Rome. Hence, it is commonly assumed that the production of opaque glasses was concentrated in major centers, which is why Rome and Alexandria are generally thought to have been important production centers for high-value or “luxury” glass.

5 Secondary Production and Consumption

5.1 The Blowing Revolution

Colorless and weakly colored green-blue blown tablewares – jugs, bowls, cups, flasks, and plates – are the most visible products of the Roman glass industry in museum collections (Figure 6). As broken fragments, they are indeed the most commonly retrieved type of glass from archeological excavations. Their widespread appearance in the first century CE represented a revolution in

production made possible by the introduction of inflation with a blowpipe, coupled with a substantial increase in the manufacture of raw glass from sand and alkali.

Before the middle of the first century BCE, the main methods for making glass vessels were limited to winding around a core, or slumping a disc of hot glass over a typically hemispherical or conical former to produce a bowl (Chapter 10.5). Open forms made by the latter method are the major component of Hellenistic and early Roman assemblages of glass. The use of polychrome canes in conjunction with this technique allowed the production of *mosaic* glass vessels – bright multicolored bowls demonstrating a wide and highly imaginative range of decoration, which implied great skill in both conceptualization and design and in its implementation (Figure 5).

The free manipulation of hot glass made possible by blowing allowed a far greater range of forms to be produced, including vessels with narrow openings (Figure 6). Blowing was fast and did not require the preparation of molds or formers and the removal of their traces when the vessel had been shaped. As there was no core material adhering to the interior, it was more favorable to the use of relatively inexpensive transparent and uncolored glass. It allowed the manufacture of vessels with much thinner walls, hence required less glass. Therefore, it resulted in an upscaling of production so that glassware became widely available to people of relatively modest means. Furthermore, it made possible the blowing of vessels into molds

Figure 5 Mosaic-footed glass bowl, Victoria and Albert Museum 969–1868. Made by first producing a polychrome disc from colored glass strips and then slumping this over a hemispherical former. of stone, ceramic, or metal, and the mass production of cylindrical and prismatic bottles for the transport and sale of liquid goods.

The invention of the blowing technique is not well understood. However, an archeological assemblage of about the right date comprises a dump of discarded and waste glass from a workshop in Jerusalem (cf. Chapter 10.5). Here, glassworkers appear to have been inflating small glass vessels by sealing the ends of folded tubes of glass and blowing the glass tubes [17]. This evocative group of material is very suggestive of the first step toward the practice of blowing glass with an iron blowpipe, but corroborative evidence and a firmer timeline are required. Whereas only a few iron blowpipes have been retrieved from Roman contexts, the glass rings remaining around the blowpipe when glass was blown, known as *moils*, are relatively common, and can include flakes of iron oxide, confirming that blowpipes were typically made of iron or steel.

5.2 Local Workshops

Most large centers of population seem to have had active glass workshops at some point but it is not always clear if these were permanent, long-term establishments or if their operation was short term and sporadic. In Britain,

for example, it appears that even in a major provincial center such as *Londinium*, glass workshops operated sporadically and glass workers were peripatetic, bringing their raw material and establishing a furnace until the fresh glass was exhausted and no more scrap glass could be obtained for recycling from the local population [18]. However, Britain was a province on the edge of the Empire and about as far away from the sources of raw glass as possible, so that permanent workshops are likely to have been a feature of regions more central or closer to the sources of glass.

Furnaces for glass working varied in both shape and size [19]. Crucibles or melting pots are relatively uncommon in the first to fourth centuries. Most furnaces at the height of the Roman Empire melted the glass in a tank, in some cases heated on the reverberatory principle. Understanding of the furnaces is limited at present as typically only their bases are preserved. Designs appear to have varied, with a circular or rectangular plan and dimensions typically less than 1 m in internal diameter. The typical fuel is likely to have been wood, where available, but agricultural by-products such as those of olive-oil extraction as well as animal dung are likely to have been used in more arid regions. For example, excavation of a workshop at Beth Shean in Israel yielded vessels covered in charred olive pits, presumably for annealing (Chapter 10.5).

5.3 Decorative Artifacts

In addition to plain or mold-blown tablewares, a range of other products were available to the Roman consumer [20]. During high-temperature work, trails or blobs of colored or colorless glass could be added to embellish the vessel. Colorless vessels could be cut or engraved, with a stone wheel or, for fine work, a rotating copper wheel with a slurry of abrasive such as quartz or emery. Diamond engraving tools were known in the time of Pliny, but it is not clear how widely they were used. Cameo glass, such as the Portland Vase, where an outer layer of glass has been cut away to reveal an underlying glass of a different color, date mainly from the late first century BCE to the early first century CE. The most sophisticated examples of glass-cutting are the *diatreta* or cage-cups of the fourth century (Chapter 10.5), of which the Lycurgus Cup (Figure 4) is an unusual example with figurative, as opposed to geometric decoration.

A small class of vessels were enameled – painted with powdered opaque glass, which was then fused to the surface (Chapter 10.6). Enameling represented a challenge in that the softening temperatures of the glass paints were frequently similar to those of the underlying vessel so that the operation was carried out by insertion of the painted vessel into the mouth of the furnace for a very short period [1]. Dating to the fourth century, another small group of artifacts is well represented in museum collections. It comprises round vessel bases with designs in gold leaf sandwiched between two layers of glass (Chapter 10.5).

With the widespread adoption of blowing, there was a marked decline in the production of strongly colored glass vessels around the middle of the first century CE. The use of strongly colored glass is then seen in the production of glass tesserae for wall mosaics. These decorated the houses of the wealthy who could sustain the more expensive raw materials and production costs of opaque glass. The tesserae appear to have been cracked off from pizza-like “cakes” of glass, typically around 8 mm thick. Colored glass was also used for beads and for minor decorative elements on certain classes of colorless vessels.

5.4 Windows and Mirrors

Glass windows were widely used to light bath houses and other public buildings while providing heat insulation. Window panes were frequently made by the *casting* process whereby the molten glass was poured onto a flat surface, pressed flat, and then manipulated into a rectangular shape by reheating and pulling with tongs. Production of windows through reheating and opening up a blown cylinder of glass (Chapter 10.8) seems to have become more common in the fourth century [21].

To make mirror glass, a large glass bubble was inflated and poured in molten lead to coat the inside. The resulting mirrors were made from trimmed fragments broken from the bubble that were set on plaster or wooden frames. They are rarely, if ever, more than a few centimeters across. A number of plano-convex transparent lens-like objects have been reported but their function is unclear. They have limited magnifying power (c. $\times 4$) and might have been used as decorative inlays in furniture or architecture. Whereas it is possible that occasional items were made to specification for technical purposes, we have no archeological evidence that there was any routine production of scientific or technical glassware. There are plenty of glass phials, which could have held medicines but also oils and perfumes, so they are not really strictly scientific or technical; some described as Roman and potentially alchemical seem to be in fact Islamic in date. Indeed, at present we have no evidence of the manipulation of glass composition for any other purpose than the modification of color or the cost and availability of raw materials.

6 Recycling, Shifts in Production, and Decline

Recycling of glass was common practice throughout the period [22]. Contemporary literary evidence indicates that scrap glass was exchanged for sulfur matches on the streets of Rome. Caches of old and broken glass have even been discovered by archeologists. A striking evidence for recycling is the barrel of scrap glass recovered from the third-century wreck of the *Iulia Felix* in the Adriatic [8].

At its height in the first to third centuries, Roman glassware was produced in two compositional categories – an antimony-decolorized glass with around 5% CaO and 2% Al_2O_3 and a manganese-decolorized variety with around 7.5% CaO and 2.7% Al_2O_3 . These are distinctive in many ways (Figure 3) and represent two primary production centers. Simple graphical analysis indicates that most glass of this period comprises one of these types or more frequently a mixture of the two, owing to the extensive practice of recycling at this time (Figure 7).

Following the apparently abrupt end of decolorization with antimony in the fourth century, a new greenish glass, richer in iron ($>1\%$ FeO), became dominant over much of the Roman world. It is thought to have been made in Egypt and was used alongside a continuation of the Mn-decolorized glass made on the Levantine coast. Over the next few centuries, a series of relatively abrupt changes in the composition of natron glass indicates shifts in the location of production within the South-East

Figure 7 Typical mixing line between Roman antimony-decolorized glass, with low Al_2O_3 , and manganese-decolorized glass, with high Al_2O_3 [22], displayed by Roman glass fragments from the Iulia Felix wreck in the Adriatic [8].

Mediterranean region (Figure 1). Over the same period, there is a gradual decline in the quality of glass made in the Levant, where the use of manganese decolorant diminished and the average soda content of the glass reduced until, in the eighth century, a bluish glass with around 12% Na_2O and 75% SiO_2 became the characteristic product (Table 1). This period of decline corresponds to the contraction of the Roman Empire and a dramatic reduction in the volume of Mediterranean trade. Indeed in the post-Roman (early medieval) societies of Europe, fresh glass from the Southeast became increasingly difficult to obtain. From Italy through to Britain, evidence of a dependence upon recycled glass becomes increasingly apparent from the end of the sixth century.

An important source of this recycled material may have been the wall mosaic and window glass of the large public buildings, which were abandoned with the decline and withdrawal of Roman administration. Mosaic tesserae were important sources of material for color as well as for raw glass; for example, cobalt-blue tesserae were mixed with colorless glass to produce translucent blue sheets for windows through to the twelfth century. Limpid blue- or green-tinted transparent glass of the eighth–ninth centuries may contain copper, antimony, and lead at high levels, which could have resulted only from extensive recycling of first–third century opaque tesserae, excluding cobalt blues, which were reserved as a source of blue pigment [22].

In western Europe, much of this recycled material was likely imported from the old Roman regions in the South. By the ninth century, it could no longer satisfy the demand for glass, which included the requirements of the growing Christian churches and monasteries. A new formulation was thus developed such that glass began to be made from local sand and potassium-rich wood ash, laying the foundations for the stained glass window industry of the high medieval period (Chapter 10.8). In the Islamic East,

natron-based glass production declined in the ninth century when the natron flux was replaced by soda-rich ash, produced by burning halophytic plants from desert and coastal environments, marking an end to the Roman tradition of glassmaking.

Although current opinion is that glass was no longer made from Egyptian natron after around 900 CE, natron-based glass continued to be in use through the thirteenth century for some purposes. The compositions of glass enamels on Romanesque copper-alloy reliquaries and plaques of the twelfth century correspond precisely to the opaque glasses of the second–third centuries. Writing around 1120 CE, the monk Theophilus tells us that these were obtained from the old buildings of the pagans (Romans) [23]. He also indicated that window glass was colored blue by mixing blue tesserae with contemporary wood ash glass. Analysis of medieval church windows supports this account [22].

7 Perspectives

The preservation of ancient cultures is tenuous. Analytical samples of heritage materials such as glass can be difficult to obtain, which is why the available data have been collected in a somewhat opportunistic and arbitrary fashion. For some regions they depend upon museum material that may date back to the early twentieth century or before. Even so, over the past 20 years, new archeological discoveries and improvements in the understanding of vessel chronology, along with a marked expansion in scientific investigations, have led to the development of a consistent model of Roman glass production.

Detailed archeological studies focused on glass assemblages at specific sites, on shipwrecks, or on the geographical distributions of specific types of glass objects are

continually enlightening our understanding of the ways in which glass was perceived, valued, used, and reused. New trace element and isotopic approaches are likely to be applied to shed light on the sources of fluxes, colorants, and opacifiers. Although several primary production sites have been identified, those of some of the major types of glass remain to be discovered whereas the possibility of primary production in the West requires more attention. Modeling and experiment offer the potential to understand better furnace operation. In this respect, the determination of oxidation states in experimental glasses could allow furnace conditions to be determined.

Alongside other evidence, this framework will allow glass to be used to yield important information on industry, trade, and the ancient economy. The wider reasons behind technological innovation and change, the movement of production locations, and the growth and decline in glass use will be amenable to investigation as our understanding of chronology and regional variation becomes more refined. In this way, the study of glass will bring new and valuable information on the inner workings and evolution of the Roman Empire itself.

Glass and the Philosophy of Matter in Antiquity

Marco Beretta

Università di Bologna, Bologna, Italy

1 Introduction

In Antiquity, glass, more than any other product made out of earthly materials, could be easily shaped and colored to imitate precious stones or mineral substances. Egyptian priests projected a religious meaning onto the mineral kingdom, such that each mineral was endowed with special properties that evoked the presence of the gods [1]. When it was discovered that glass could imitate lapis lazuli, Egyptian craftsmen began to reflect upon the properties of matter and the value that should be attributed to imitations. Were these mere counterfeits or faithful replicas of the natural stones? This was a critical question because, with the XVIIIth dynasty (c. 1543–1292 BCE), the production and trade of both artificial and natural lapis lazuli became an important aspect of Egyptian culture and religious rituals.

The Egyptian glassmaking tradition survived in Hellenistic Alexandria, exporting both technical know-how and theoretical insights to Palestine and, during the Roman Empire, along the Mediterranean coastline. Attention to archeological data in particular reveals that Egypt played an exceptionally important role in directing the interest of early Greek philosophers and naturalists on the properties of glass.

Of particular importance in this respect was the philosophy of matter first expounded by Empedocles of Agrigento (483–424) according to which everything in the sublunar world (the Earth and its atmosphere) was made up of various proportions of the four elements, fire, air, water, and earth. When Plato (c. 428–347) and his former disciple

Aristotle (384–322) subsequently went one step further with their own explanations for the transformations undergone by these elements, their theories had an obvious bearing on glass, whose marvelous properties such as natural luster and transparency required a rational account in terms of the action of fire upon a variety of earthly substances. And not only was glass representing the dramatic transformation of insignificant raw materials into a remarkable substance akin to gems, but it also had many common features with metals in general. Hence, glass became closely involved in alchemy when metal transmutation became an important goal of this *Sacred Art*, and such efforts could only increase after the technical revolution triggered by the invention of glassblowing during the first century BCE.

Before examining glass within the context of ancient philosophy of matter, however, we will have to go back in time and consider how this material was originally considered in Mesopotamia and in Egypt. From Empedocles' to Plato's and Aristotle's theories, we will then briefly present the basic relevant concepts before delving into the mutual relationships of glass and alchemy. Finally, the role played by Byzantium in the transmission of the alchemical tradition will be summarized.

2 Near Eastern Views on Glass

2.1 Mesopotamia

From about the twelfth century BCE, Mesopotamian glass and medical texts bore a resemblance in their literary form: they prescribed instructions in the form of recipes, and some even recommended religious rituals and prayers, invoking the need to perform certain experiments during propitious days ([2], Chapter 10.11).

Reviewers: F. Dell'Acqua, Dipartimento di Scienze del Patrimonio Culturale, Università degli Studi di Salerno, Fisciano, Italy
M. Martelli, Humboldt-Universität zu Berlin Institut für Klassische Philologie, Berlin, Germany

According to these early Mesopotamian recipes, the chemical operations required to produce colored glass were preceded with a ritual including the worship of images and a libation offering; when the glass was placed into the kiln, a sheep was sacrificed before images of the Gods. Such rites were important because their association with a holy discipline such as medicine underlines the scientific and literary dignity of glassmaking. One of the most important achievements of Mesopotamian glassmaking was the imitation of lapis lazuli. Given the importance of these gems in near-Eastern art and culture, the ability to produce notable quantities of artificial stone represented an important technological advance, although glass was still valued as highly as gold.

Another feature revealed by Mesopotamian texts, which would have important consequences for the history of glassmaking, was the definition of glass itself: the term *bašlu abnu* (molten stone), which announced the Greek *lithos chytè* (molten stone), eventually used by Herodotus (c. 484–420) [3] and other Greek authors. The reference to the chemical operation of melting is significant because the fusing property of glass was shared by other mineral substances, especially metals. In this respect, it seems that at a very early stage glass was not seen as an entirely artificial product but as a natural stone which, like metals, could be fused and modified.

2.2 Egypt

Although the influence of Mesopotamian glassmaking on Egyptian craftsmen is now generally acknowledged, the priority disputes over the invention of this material have overshadowed the different approaches and technologies developed within the two civilizations. In fact, Egyptian craftsmen displayed an extended knowledge of primary ingredients, developed advanced metallurgical techniques that led them to produce a richer variety of colors, and, last but not least, manifested a theoretical interest in the classification of glass within a *philosophy of matter* apparently absent from Mesopotamian texts.

The glass industry made its appearance in Egypt from 1400 BCE during the reign of Akhenaten (r. c. 1354–1338). Like in Mesopotamia, the invention of glass probably derived from the crafts of faience and glaze. These materials consisted of the same ingredients – silica, alkali oxides, and lime in modern parlance – but their technical treatment was completely different, thus resulting in many different vitreous bodies. Both glass and faience were treated as artificial precious stones, however, and Egyptian craftsmen seem to have mastered both techniques with the greatest dexterity.

At least between 1400 and 1050 BCE, glass was of great importance in Egyptian culture for the production of

amulets, beads, vessels, inlays, and the imitation of precious stones. Probably because glass could imitate so many materials, the Egyptians did not coin a specific name to denote it until the third century CE, when the demotic *yl* was used for the first time in the magical papyrus of London [4].

Egyptian craftsmen, like their Mesopotamian counterparts, also defined glass as a “molten stone” or “molten precious stone” (*aA.t-wdH*). Going farther than their predecessors, however, they included glass artifacts within a comprehensive classification of metals and mineral products without finding it necessary to establish a clear-cut distinction between glass and faience, on the one hand, and glazing mineral stones on the other. One definition of glass appropriated the term faience, *THn.t*, which was derived from the verb *THn*: to sparkle, to scintillate, the lightning flash. As the etymology would have been equally effective to denote colored glass, the term later became synonymous with this new artifact.

While sharing the same property of being meltable, substances such as gold and lapis lazuli differed essentially by their qualities of color and brilliance. According to Hecataeus of Abdera (late fourth century BCE), a Greek skeptic philosopher who wrote a book now lost on the history of Egypt, Egyptians believed in a principle of matter which, divided into four elements, became the basis of all living beings [5]. The relation between these elements and the importance attributed by Egyptians to colors in order to classify the products of the mixtures of the four elements would eventually find an important echo in the Greek philosophy of matter.

Because the gods’ influence over the mineral kingdom was so pervasive, craftsmen who were engaged in the manipulation of metals and stones were in touch with godly particles and fluids, and their capacity to transform matter thus placed them in the position of demiurges (Figure 1). It is not without significance that there was no term denoting glassmakers in Mesopotamia whereas in Egypt *irw hsb* denoted the craft of “makers of (artificial) lapis lazuli,” thus showing the professionalization of a skill that would enjoy significant importance within Egyptian society and culture. As a matter of fact, craftsmen enjoyed a higher social status in Egypt than in Classical Graeco-Roman economic contexts. In Egypt, claimed the Greek physician Galen (c. 129–216), new artisanal discoveries were always submitted to the approval of scholars, who provided public notice of the new inventions through inscriptions fixed on sanctuary columns. It was the tradition of omitting inventors’ names from these inscriptions, which, according to Galen [6], caused a multitude of anonymous writings on occult sciences to be attributed to the god Hermes Trismegistus, the founder of all wisdom.

3 The Glass of the Greek Philosophers

3.1 From Empedocles to Plato

Even though scholars long raised doubts concerning how much was actually known in archaic Greece about glass, today it is clear that techniques had then been imported from Egypt to imitate ceramics and were already used widely. Homer's works, which are often used to show the absence of references to glass in the eighth century BCE, in reality contain many references to a substance called *kyanos* designating a blue glass paste used to decorate temples [7] and warriors' armor. In other passages of Homer and in Philostratus [8] and Aristotle after him, the term *kyanos* is used as an adjective designating the blue, iridescent color of stones, animals, and objects. In another sense *kyanos* designated an actual stone – a natural product that Pliny the Elder (23–79) identified in his *Natural history* [9a] with a blue pigment (*caeruleum*) and by his modern commentators as azurite – a blue stone similar to lapis lazuli.

The Greeks identified metals with products of mineral extraction that were meltable. These included not only real metals such as gold, silver, and copper but also composite bodies, such as glass and some mineral pigments, which were not discernible within ancient philosophies of

matter and would be today designated as metallic substances. What curiously associated these materials was solely their properties of being products of mineral extraction and, above all, of being meltable materials that could change form if submitted to the action of fire through metallurgical techniques.

As already noted, the most influential philosophy of matter in Antiquity was that of Empedocles. Probably the now lost treatise on metals occupied an important place in his poem *On Nature*. But the important point is that, from the advent of this theory, it became necessary to give an empirical foundation to the macroscopic changes visible in a material. On the assumptions that all bodies release effluences and at the same time have pores capable of absorbing other effluences commensurable with them, Empedocles understood that metals “like all other bodies possess a structure” [10] so that the differences among the elements and the compounds were due to the different configurations of their aggregate of particles.

Empedocles' theory of pores was taken up again by his pupil, Gorgias (c. 483–376 BCE) in order to explain the property common to bronze, silver, and glass of forming mirrors capable of concentrating sunlight and acting as burning mirrors [11]. By the way, we must note that, contrary to what is still often believed, the Greeks did make glass mirrors and were well aware of the differing reflecting properties of metals. To establish a distinction of this kind, it was in fact necessary to be much more familiar with the workings of glass and metals than attested to by fragmentary archeological proofs and, above all, by late Latin texts.

Empedocles' philosophical intuition on the structure of matter, based at least in part on his knowledge of metallurgical techniques, received further and more profound consideration by Plato. In his dialogue *Statesman* [12], no distinction was made between “gold and silver, and everything that is mined,” showing the connection between the identification of metals with the technique of their extraction. Metals were substances extracted from the Earth, which, when subjected to the action of fire, were behaving in the same way. Regarding glass, it is interesting to note that one of the first occurrences of the term *hyalos* in the explicit context of natural philosophy is found in Plato's *Timaeus* [13a], his great cosmological dialogue.

This introduction of the term *hyalos* in the fifth century BCE brought with it a more precise understanding of glass. According to some philologists, the substantive *hyalos* derived from the verb *heyin* (to rain), signifying water droplet, whereas others say that it derives from *hals* (salt): the former term exalts the physical characteristics of glass – particularly its brightness and transparency – whereas the latter alludes to its chemical constitution. Whatever

the correct explanation is, in both cases physics and technology were at the basis of the Greek definition of glass.

As for the elements, Plato explained in *Timaeus* that the triangle was their building block so that the four of them represented the four fundamental regular polyhedra, namely, the tetrahedron (fire), cube (earth), octahedron (air), and icosahedron (water) [13b]. In terms of a balanced reaction, the vaporization of water upon heating was, for instance, seen as the rearrangement of the 20 equilateral triangles of one water icosahedron into the 4 triangles of one fire tetrahedron and the 16 triangles of two water octahedra [13c].

In *Timaeus*, Plato could then discuss the interplay of fire and water in metals and define glass [13d] as a mixture of water particles (in a larger proportion) and of earth, which, when subjected to the action of the particles of fire reached the molten state. It is fusibility, therefore, which Plato also attributed to metals, that defined the material character of glass. This concept represented a fundamental step forward in antique metallurgy and eventually also involved a better understanding of what glass was.

3.2 Aristotle

Although paying careful attention to empirical research, Aristotle's primary interest, without doubt, was to construct a coherent philosophy of matter capable of overcoming the limits encountered by that of Plato. This is what he did in the in the fourth book of his *Meteorology* where attention was duly paid to metals, in general, and to glass, in particular. Without falling into the wild speculations of earlier thinkers, Aristotle rejected Plato's geometrical approach to posit instead that the elements should rather be accounted for in terms of four fundamental *qualities*, namely hot, cold, dry, and humid. Fire was then dry and hot, air dry and cold, water cold and humid, and earth dry and cold so that all transformations within the sublunar world was taking place through exchanges of these four qualities.

On this basis, Aristotle proposed elaborate interpretations for the cause of the chemical changes to which matter was subjected. He took his cues from widespread practical and craftsmanly activities such as that of the art of the potter, when speaking of the properties of clay, or the treatment of oil, when describing differences in the solubility of liquids. Likewise, the properties of solid bodies were sifted through a system of categories derived from arts and techniques. In this way, Aristotle proposed to distinguish bodies according to a comprehensive property flow-chart: "to be apt or inapt to solidify, melt, be softened by heat, be softened by water, bend, break, be fragmented, impressed, moulded, squeezed; to be tractile or non-tractile, malleable or non-malleable, to be fissile

or non-fissile, apt or inapt to be cut; to be viscous or friable, compressible or incompressible, combustible or incombustible, to be apt or inapt to give off fumes" [14a].

Aristotle then imagined that the formation of metals and many other mineral bodies were due to the two types of exhalations generated by the Sun's heat: the first liberated watery vapor, which constituted water and insinuated itself into the bodies of which it was a component; the second was dry and very inflammable, deriving directly from the earth. Not limiting himself to characterize metals as meltable bodies extracted from mines, as Plato did, Aristotle also sought to find out the cause of their meltability. He assigned it to the vaporous or watery exhalation, which, thanks to its intrinsic humidity, rendered these bodies susceptible to melting and thereby to reaching the liquid state. Further, the different degrees of fusibility of various metals were, according to Aristotle, due to different proportions of the two basic elements, water and earth, since "all determinate bodies in our world involve earth and water. Every body shows the quality of that element which predominates in it" [14b]. And it appeared that the aqueous element often seemed to prevail: "gold, then, and silver and copper and tin and lead and glass and many nameless stones are of water; for they are all melted by heat" [14c].

In light of Aristotle's classification, one could think that the idea of defining glass as *hyalos*, deriving from the verb *to rain* was not altogether extraneous from the chemical property of this material to reach a molten state at high temperatures. The possibility of producing transparent glass was conditioned by the availability of furnaces capable of reaching temperatures above 1000 °C. Therefore, the substitution in the fourth century BCE of the terms *kyanos* and *lithos chytê* for *hyalos* might have reflected an awareness of technological progress achieved especially in the art of glassmaking.

From this definition, it clearly appears that the Ancients considered the philosophy of matter as distinct from manipulative procedures, thereby allowing them to recognize constitutive differences between various classes of minerals. In fact, in the majority of citations assembled here, it was technique that rendered possible the general definition of a specific class of minerals.

4 Glass and Alchemy

4.1 Art as Imitating Nature

References to glass are found not only in philosophical texts, but in far greater measure in alchemical practices that were half way between philosophical speculation and empirical experimentation. Ancient alchemy played a central role primarily because it was inherent to the

Figure 2 Oil lamp with the illustration of an artisan blowing glass in a pipe. At the center, a glass furnace; on the left, another worker is holding the finished product. First century CE. Source: Courtesy Museo del Belriguardo, inv. 52196, Ferrara.

techniques and knowledge that were essential to the production of glass (Figure 2). The construction and development of furnaces capable of reaching ever higher temperatures, the acquired skill of combining an ever-increasing number of ingredients, the chemical techniques of coloration just as those for counterfeiting gems and precious stones were all aspects shared by craftsmen and alchemists alike [15, 16].

It is difficult, and perhaps historically improper, to try to relate the production of glass by artisans to an attempt at providing metallurgical production with a theoretical and philosophical framework that would have been completely extraneous to practical needs. It is nonetheless odd that historians of glass have neglected alchemical sources by concentrating exclusively on archeological remains and on those texts, by Pliny the Elder in the lead, that have little technical content and, above all, do not reflect the actually widespread knowledge of this material in the ancient world.

If the procedures of the Greek alchemists mostly derived from the technical tradition of Egyptian artisans,

they also depended upon philosophies of matter which, from the pre-Socratics onward, had tried to give rational explanations to the changes wrought upon matter by the action of fire. In most of the alchemical texts of late Antiquity, this is why we find among the authorities and founders of the alchemy the names of Thales, Pythagoras, Democritus, Plato, and Aristotle mixed with those of Egyptian sages.

There is another profound reason why the development of Greek alchemy, which flowered in the Alexandrine epoch, was bound to classical philosophy. The idea of the transmutation among substances was an assumption not only shared by the main philosophies of matter in Antiquity, but for Aristotle it constituted one of the most important keys for explaining chemical combination in terms of only the four elements and their qualities. If all bodies of the sublunar world were composed of air, water, earth, and fire, then one could transform one into another by changing the proportions of their constituents.

This basic philosophy permits us to understand how the identities of substances listed in the lapidaries, and in other works of this type, were so often confused with counterfeits or with such artificial products as glass. If one accepted the possibility of transmutations, then a sharp distinction between natural and manufactured products was clearly inconceivable. Hence, glass was often confused, or perhaps more correctly, set in relation to various crystals, metals, stones, and gems, which, in their turn, could assume characteristics similar to those it displayed.

In connection with the importance that the philosophers attributed to transmutation for explaining chemical reactions, another principle must be recognized for its enormous influence on the development of classical alchemy. We have already emphasized that one of the chief preoccupations of Greek philosophers was not to oppose art (i.e. man's operations) and nature. Attempts at re-evaluating the former were, in fact, directly conditioned by the ability to demonstrate its intimacy with the latter. *Art imitates nature* was thus a common saying or, as reported by Pliny the Elder's legendary history on the origins of metals and glass, nature itself generates art. In this regard, it is significant that in Plato's *Timaeus* the creator of the universe is called *demiourgos*, the artisan.

In the field of chemistry, the coexistence of art and nature was stressed repeatedly. Speaking of a sand with special properties, Theophrastus (c. 371–287), Aristotle's main disciple, for instance, noticed a means of imitating nature efficaciously in experiment and in technology [17], thereby outlining a theoretical principle that was to be carried out by classical alchemy.

Once they identified the relevant philosophical principles, alchemists could rely on an ample supply of

technical information. Even though sufficient direct evidence is lacking, the frequent references to the learning of the Egyptians, together with the Egyptian and mid-Eastern origin of most of the Greek alchemists, likely confirm the important influence of Egyptian arts and metallurgical techniques.

4.2 Bolus of Mendes

The earliest alchemist is Bolus of Mendes, also known as Pseudo-Democritus and long confused by late antique authors with the philosopher–atomist Democritus of Abdera (c. 470–380). Even though information is scarce concerning Bolus and his life, a rather corrupt lexicon compiled toward the end of the tenth century, identified him as a follower of Pythagorean philosophy and as the author of various works among which was one dedicated to “the sympathies and antipathies of stones.” The chronology of Bolus’ life is still more difficult to establish with any precision. He was long thought to have lived in the second century BCE. However, his use of oriental sources such as Zoroaster and Ostanès translated into Greek around the first century of our era situates his life in a later period.

In his *Letters to Lucilius*, the Roman stoic philosopher Seneca (4 BCE–65) still confused Bolus with Democritus of Abdera when he wrote [18]: “It seems to have quite slipped your memory that this same Democritus discovered how ivory could be softened, how, by boiling, a pebble could be transformed into an emerald – the same process used even to–day for colouring stones which are found to be amenable to the treatment!” The passage is revealing not only because it places the life of Bolus before 60 CE when the *Letters to Lucilius* were written, but shows how counterfeiting precious stones, primarily emerald, by using glass or rock crystal was not part of the craftsman tradition but was invented by an alchemist, or – as Seneca still confuses it, by a philosopher. Furthermore, as shown by the alchemical papyri of Leyden and Stockholm [19], the recipes for counterfeiting emerald represent a considerable part of late antique alchemical literature so that these recipes should have originated in Bolus’ work.

Even though available sources are indirect and fragmentary, it is not difficult to understand that Bolus was a figure of certain importance and originality in the panorama of this period. The dating of Bolus between the first century BCE and the first decades of the next century is important because we know, as Pliny the Elder recounts in detail [9b], that it was just in this period that glassmaking made important technological progress. Of course, it cannot be claimed that alchemy directly originated from the development of glassmaking but rather, contrary to what has been hitherto supposed, that close relations

were usually posited between the two arts as exemplified by the Christian philosopher Aeneas of Gaza (fl. fifth century CE) who wrote in *Theophrastus*, his dialogue on the soul: “Change of matter to a better state is not implausible for, among us, experts in materials, taking silver and tin, making their form disappear, melting them down together and colouring them, and so changing the matter in something grander, have produced excellent gold. Again, sand is scattered and soda is abundant everywhere, but human skill has made glass out of them, new and transparent” [20].

4.3 Glass and Counterfeited Stones

As already stressed, the art of glassmaking offered a splendid example of how common materials could be transformed by the furnace into a noble and brilliant material (Figure 3). This quality became apparent in the counterfeiting of precious stones. During the Hellenistic era, gems rapidly became luxury items, which were particularly sought after for their virtues. Pompeius Magnus (106–48) and Julius Caesar (100–44) were the first to build up important collections. During his third triumph (61 BCE), Pompeius brought to Rome what he believed to be his most precious war booty, the *myrrina vasa*, extraordinarily beautiful vases made of such a precious material that two generations later the Emperor Nero (r. 54–68) managed to ensure for himself one single bowl at the astronomical price of 1 000 000 sesterces. Without the help of archeological evidence, the identification of *myrra* has been so problematic that for a long period this mysterious substance was thought to be *millefiori* glass [21]. Only recently has it been demonstrated beyond doubt that *myrra* should rather be identified with fluorite.

Given the exceptional rarity of this mineral, Pliny thus reported that glass was used to imitate and counterfeit *myrra*. In view of the new spreading passion for gems and the peak of perfection reached by Roman glassmakers, Pliny mentioned in several chapters of his *Natural History* [9c] “how to make genuine stones of one variety into false stones of another” while lamenting that “to distinguish genuine and false gemstones is extremely difficult.” In addition, he mentioned the existence of treatises (*commentarii*), whose authors he preferred to omit, which gave “instructions how to stain crystal in such a way as to imitate smaragdus and other transparent stones, how to make sardonius of sarda, and other gems in a similar manner.”

Likewise, Pliny mentioned treatises devoted to glass. The circulation of this literature is of the greatest importance because it attests to the existence of authors who decided to write on topics that, for centuries, had been either kept secret or treated in general and encyclopedic works such as Pliny’s. The diffusion of this literature was

Figure 3 Pharmaceutical and chemical (?) glassware found in the Casa del Fabbro in Pompeii during the first half of the twentieth century. All items destroyed during WWII. Source: Courtesy Soprintendenza Archeologica di Pompei.

certainly justified by the amazing dexterity reached by Roman glassmakers in imitating precious stones.

More common stones were also worked in such ways that they soon became luxury objects. Rock crystal was so highly regarded by the Romans that at the time of Pliny a single dipper was paid 150 000 sesterces by “a respectable married woman” [9d]. As a consequence of these follies, the manufacture of imitation and counterfeit was encouraged. “Glassware, said Pliny [9e] on this matters, has now come to resemble rock-crystal in a remarkable manner, but the effect has been to flout the laws of nature and actually to increase the value of the former without diminishing that of the latter.” That fake crystal artifacts did not cause prices to fall was probably due to the perfection of the counterfeits, which, without the help of chemical analysis, often remain today difficult to distinguish from true ones. By combining glass to crystal Roman artisan were able to imitate beryl, a gem particularly admired also because of his virtues [9f].

By the end of the second century CE, the connection between glassmaking, gold, and precious stones was

embodied in the description in the Apocalypse of Saint John [18, 21] of the new Jerusalem where we read: “And the building of the wall thereof was of jasper stone: but the city itself pure gold, like to clear glass.”

As for opal, Pliny said that “there is no stone which is harder to distinguish from the original when it is counterfeited in glass by a cunning craftsman. The only test is by sunlight” [9g]. Also *carbunculi* (rubies?) were “counterfeited very realistically in glass, but, as with other gems, the false ones can be detected on a grindstone, for their substance is softer and brittle” [9h]. Whereas “no gemstone is more easily counterfeited by means of imitations in “glass” than “topaz,” Pliny added [9i], many other gems such as jasper, zephyr (?) were mentioned by him in connection to glassmaking. The imitation industry must have been flourishing at the same time when glassblowing was a widespread technique because, some decades before Pliny, the Roman encyclopedist Varro (116–27), noted in his *Saturae Menippeae* [22] that “to an inexperienced eye, a shell sometimes looks like a pearl, and glass like emerald” [22]. These fraudulent practices became

eventually so common that the first Church fathers often took it as an example in their writings to show the deceptive nature of glass products.

4.4 An Elusive Art

If imitation was as ancient a practice as glassmaking itself, treatises explicitly devoted to this art must have been relatively recent as no reference to them can be found in earlier sources. This literature, which would eventually be embodied in alchemical recipes, was thus contemporary to the extraordinary development of glassmaking. Although it is impossible to ascertain a direct relation between them, the number of distinguished authors who wrote extensively on the marvelous nature and history of this material makes us conclude that the progress achieved in the art also inspired a systematic reflection on the influence of glassmaking upon the traditional philosophy of matter.

After enumerating gems and their imitations, Pliny concluded his *Natural History* by addressing his reader with the following interesting statement [9j]: “We must not forget to mention that gold, for which all mankind has so mad a passion, comes scarcely tenth in the list of valuables, while silver, with which we purchase gold, is almost as low as twentieth.” Because alchemy, from the Middle Age onward, has been principally identified with the art of transmuting vile metals into gold or with the *chrysopoeia*, the hierarchy of valuables mentioned by Pliny placing gems in the first nine positions, provided an authoritative reason why craftsmen preferred to produce false gems and precious stones rather than embarking in what would eventually be the main occupation of alchemists. In addition to this argument, the importance of which is usually underestimated, the existence of a literature on glassmaking reveals that it was in this context that the first systematic ideas upon the possibility of imitating minerals took place for the first time.

The fact that Pliny deliberately chose not to mention the name of the authors of these treatises shows that a debate on the relation between natural and artificial stones was particularly lively and that the ambition of creating gems by the chemical arts was regarded with contempt by traditional naturalists. Inspired by a conservative philosophical standpoint Pliny, like Seneca, despised the pretentious attitude of these craftsmen who contended with nature for the act of creation. The position held by ancient philosophers seemed to be incompatible with the proliferation of opinions and practices, which, in the eyes of Pliny and Seneca, revealed the cultural and moral decadence of their contemporaries. The high social status of both authors justified their

negative attitude toward the *Commentarii* and their authors, but one wonders whether their perceptive attention on the recent technical progress was not a sign of the power of attraction they exerted on the intellectuals of the time.

Additionally, there were authors who held a different opinion to develop new theories on the properties of matter by taking the chemical arts as point of departure. This was the case of the enthusiastic followers of the Pythagorean philosophy, which spread in Rome as early as the first century BCE and made systematic efforts to combine the arts with magic and philosophy. While describing the problematic properties of the diamond, Pliny remarked [9k]: “Now throughout the whole of this work I have tried to illustrate the agreement and disagreement that exist in Nature, the Greek term of which are respectively ‘sympathia’, or ‘natural affinity’, and ‘antipathia’ or ‘natural aversion’. Here more clearly than anywhere can these principles be discerned.”

Pliny probably referred to a work entitled *Peri antipatheion kai sympatheion lithon* which evoked a doctrine that was exerting a considerable influence on natural philosophy. The author of this work is uncertain, although, given its astrological contents, Bolus of Mendes seems the most likely candidate [23]. Whatever the real identity of the alchemist was, it is important to point out the connection between the appearance of Bolus’ works and the development of glassmaking, an art which enjoyed both a high social reputation and a considerable “philosophical” importance. Such a reputation, reflected in the publication of treatises devoted to this topic, reached its peak during the first century CE when Pliny associated this literature with fraud because he felt the threatening effects of its pervasive diffusion. The chronological coincidence between the appearance of the work of the Egyptian alchemist and the progress made in glassmaking is of crucial importance because Bolus was the first author who believed that one metal might be made from another [23] and clearly referred to the possibility of the alchemical operation of transmuting substances by giving practical instructions.

5 The Byzantine Connection

Whereas many Latin authors explicitly referred to alchemical authors during the first two centuries CE, the Latin West witnessed a rapid decline of scholarly knowledge after the Barbarian invasions and fall of the Western Roman Empire. From the third century CE onward, the pursuits in alchemical research thus remained confined within the Greek and then Byzantine tradition.

Figure 4 *Garden of Eden* mosaic decorating the vault of the Galla Placidia Mausoleum, Ravenna. First half of the Vth century (after 425).

Glassmaking progressively migrated from the Roman centers of production to the south Eastern capital and cities. Together with several Syrian centers, the Alexandrine area and Ravenna (Figure 4), Constantinople represented from the first half of the fourth century CE to the end of the sixth a cultural site capable of assuring, though briefly, favorable conditions for scholarly and technical research.

In this favorable context, the presence of an important community of glassmakers is attested in Constantinople. Unfortunately, apart from massive archeological remains, our knowledge of the Byzantine glass production and of its uses is confined to exceedingly few literary sources, most of which are late and medieval. But spectacular evidence for a flourishing glass industry during the early centuries (fourth to sixth centuries CE) of Byzantium is undoubtedly the monumental mosaics which adorned the newly conceived basilicas and mausoleums.

The case of alchemy shows that Byzantine culture played a crucial role in directing the heritage of the

Greco-Egyptian tradition onto a new path. The corpus of ancient alchemical writings was collected probably for the first time in Constantinople between the seventh and the beginning of the eleventh century, when the *Codex Marcianus Gr. 299* was compiled. This manuscript, preserved in the Biblioteca Marciana in Venice, is the primary source of most of the known ancient alchemical texts. It includes not only the writings of Pseudo-Democritus and Zosimus of Panopolis (third to fourth centuries), among others, but also of Byzantine authors such as Stephanos of Alexandria (c. 550–before 638) and lists the titles of lost texts attributed to authors bearing the names of the Byzantine Emperors Justinian (r. 527–565) and Heraclius (r. 610–641), indicating that alchemy attained an unprecedented high cultural and social status in Byzantium.

The remarkable strength and prestige of the Byzantine alchemical tradition is further evidenced by the *Epistle on the Making of Gold* of Michael Psellos (1018–after 1081), the most influential intellectual of the period, where metal transmutation was accounted for in terms of the theory of the four elements [24]. Although this work does not contain anything particularly original, it demonstrates that alchemy was an integral part of high Byzantine cultural circles where, along with astrology, alchemy was likely included in higher education.

The Byzantine contribution to the alchemical corpus consisted of several recipes dealing with, among other things, glass-making, the coloring of precious stones and the manufacture of pearls. It is probable that the prosperous glass industry and its prominent role in the architectural decoration of Byzantine churches and basilicas were sources of inspiration for the alchemists in their search for the transmutation of matter. This hypothesis finds a confirmation in a work of Stephanos of Alexandria included in a manuscript, the *Parisinus Ms. 2327* of the Bibliothèque Nationale de France, where the author described in several recipes the fabrication of precious stones by colored glass and enamels.

Many of these recipes were probably coming from the Greek-Egyptian tradition. Without textual evidence, however, it is impossible to determine what exactly was added in Byzantium. It is interesting to point out once again that the progress of glassmaking went hand in hand with the development of alchemy (Figure 5). The earliest explicit definitions of this discipline as *Sacred art* during the fifth century coincided with a widespread experimentation with new glass techniques. It is therefore not surprising that the definition of transmutation set forth by Aeneas of Gaza took glassmaking as his point of departure.

Figure 5 Glass alchemical alembics illustrating the Codex Parisinus 2327 thirteenth century manuscript of Mary the Jewess' *On Furnaces and Instruments* (c. second to third century) as quoted by Zosimus of Panopolis [25].

6 Perspectives

The Egyptian glassmaking tradition survived in Hellenistic Alexandria, exporting both technical know-how and theoretical insights to Palestine and, during the Roman Empire, along the Mediterranean coastline. Such an influence explains the Greek alchemists' admiration for Egyptian culture. The survival of the *Marcianus graecus* ensured a future to the Greek alchemical tradition and its acquisition by the Byzantine cardinal Bessarion (1430–1472) probably favored its study in the West after 1468 when it was donated to the Biblioteca Marciana in Venice. However, interest in alchemy and in its connection with glass had then already been raised in the Western and Latin culture. Ideas circulated in the Mediterranean along with commodities and technical knowledge. Thus, the development of alchemy, like glassmaking, was the result of a fusion of multicultural traditions. Inasmuch as ancient alchemy was characterized by a remarkable attention to the chemical arts, we must always bear in mind that its first definition regarded it as a “holy” and “sacred” art, and that its philosophical and spiritual background were no less essential features of its identity than divination and magic were connotative elements of astrology. This characteristic of ancient alchemy once more underlines a debt to

Egyptian culture and religion. Religion, philosophy, and chemical know-how converged into the creation of a new body of knowledge, which remained prosperous even when all the other natural sciences were declining during the Hellenistic epoch and Late Antiquity. Historians of ancient science have neglected the remarkable development of chemical arts and the fecund connections they entertained with their culture. The history of ancient glass shows by contrast how useful it is to follow the impact of this technology among learned circles and how its breakthroughs have inspired philosophers of nature and alchemists alike to develop new ideas on the architecture of matter.

10.5

Ancient Glassworking

E. Marianne Stern

Amsterdam, The Netherlands

1 Introduction

Glassworking was a significant component of ancient technology. Tracing its evolution thus contributes to a better understanding of ancient societies especially since glass became a ubiquitous material of dual practical and aesthetic interest. The history of ancient glassworking is in addition relevant to modern technology or even to marketing. Whereas industrial processes such as flame finish (Chapters 3.12 and 6.7) and brand packaging still rely on innovations dating back to antiquity, most of the methods practiced today in art glass studios were already in use in the first century of our era.

Glass was a by-product of metallurgy and, particularly, of ceramics. Therefore, it should come as no surprise that glass artifacts initially imitated metal and pottery work. It took of course some time to recognize the original properties of the new material and to take advantage of them in new processes. Some techniques are still well known so that historians are paying more attention to those that disappeared, often after having given rise to outstanding masterpieces. Ancient glass has kept various defects as a memory of its fabrication. Toolmarks are important because traces of cutting, pinching, stretching, twisting, indenting, grinding, or polishing relate to the processes themselves. In addition, air bubbles, folds, or chillmarks represent a frozen image of the movement of the glass during shaping. But the interpretation of these features is not always unambiguous because blowing, sagging, and pressing can, for instance, cause bubbles to stretch in the same direction. As for idiosyncrasies like lopsided ribs and scratches in unexplainable places, they too carry information that has to be unraveled.

Current research on ancient glass-forming techniques thus also relies on theoretical reconstructions, production of replicas, and ethnographic research. All three require experiments, be they as confirmation of the feasibility of the suggested technique or as test of ideas for making reliable replicas. Any theoretical reconstruction of a technique needs to explain all the details and idiosyncrasies provided by the ancient artifact and to agree with the technological shelf available at the time and location of its production. If experiments are needed to test the feasibility of a hypothesis, they do not need to generate a perfect replica. Successful experiments are instructive only insofar as they demonstrate the feasibility of a production method. They do not represent incontrovertible evidence for the proposed technique. Not only more than one method might achieve a specific result but, like their modern counterparts, ancient artisans were likely wont to develop their own way of doing things.

It is beyond the scope of the present chapter to review all these aspects and, in particular, all diverging propositions that have been discussed in the literature. Rather, our goal here is to stress the inventiveness and artistry of ancient glassworkers by showing how they took advantage of the unique properties of glass that are discussed in many other chapters of this Encyclopedia. Material constraints will first be presented especially in terms of viscosity, temperature, and expansibility. That for 15 centuries rather viscous glass was shaped will be illustrated by techniques such as core forming, casting, and mold pressing. Excluding flat glass, which is dealt with in Chapter 10.8, the new possibilities offered by blowing will then be described. Workshops and the social and economic aspects of glassworking will finally be discussed along with some of the reasons why glass met with so much success in antiquity.

In preamble, however, it needs to be stressed that a major problem of reconstructing early techniques is that

Reviewers: S. Fünfschilling, Augusta Raurica, Augst, Switzerland
D. Ignatiadou, National Archaeological Museum, Athens, Greece

a glassworking furnace predating blowing has not yet been identified beyond doubt. Although potter kilns could have been used for firing glass in molds and preparing flat glass [1], accessible, open heat sources were needed for hot manipulation and tooling. Use might have been made of mobile firepots like those used by Egyptian metal smiths in the third millennium BCE or of shaft furnaces that deteriorated without leaving a trace. One would then understand why a workshop at Rhodes of the Hellenistic period (third to first centuries BCE) showed no trace of a furnace although tools and waste from bead and vessel production as well as thousands of beads, canes, and chunks of raw glass were found [2].

2 Basic Features of Glass Shaping

2.1 Physical Conditions

Every glass-making operation is performed under well-defined conditions characterized by fixed viscosities (Chapters 1.1 and 4.1) and, therefore, fixed temperatures for a given composition (Figure 1). But neither concept existed before the seventeenth century. Whether glass was made from raw materials or simply shaped, it was its hotness and workability that were gauged from its color and its movement on a tool. Of particular importance were three colors interpreted as *heat* indicators by Late Bronze-Age glassmakers: *glowing red*, *glowing*

green/yellow (meaning perhaps orange/yellow), and *glowing golden yellow*, the highest heat they could reach [3].

We now know that a typical Roman glass (Chapter 10.3) was sufficiently homogeneous at 1050–1150 °C, the range at which it was gathered from a pot or a tank furnace. The outer skin of the gob needed to be cooled to become a bit more viscous for blowing between 970 and 1020 °C, the rather narrow range where the glass was neither too rigid nor too soft so that shaping it on the blowpipe was readily controlled. It became possible to draw long, thin canes at around 930–950 °C when a thread could be trailed from one tool onto or around another. Above about 900 °C, one could have pinched, poked, bent, pulled, and manipulated the soft glass with handheld tools or *marvered* it on a flat surface (i.e. roll it back and forth). Flattening was an extreme form of sagging. A sizeable chunk of raw glass began to deform and sag outwardly at about 830–875 °C. It lost its shape and flattened to an equilibrium thickness of about 0.7 cm (Chapter 1.4) while its edges contracted [1] and tended to become circular as a result of surface energy minimization. One piece fused to another from 715 °C whereas the lower end of the working range was about 600 °C, the temperature at which glass began to bend or sag under its own weight.

Glass adhered to metals and ceramics as long as both materials were hot. But a temperature difference was crucial to the success of operations: upon gathering, the tip of the blowpipe had to be cooler than the glass to let it contract around it whereas the opposite held true to let

Figure 1 Viscosity ranges for glassworking operations and viscosity–temperature relationship of the typical Roman glass of the Embiez shipwreck (solid curve, P. Richet, personal communication). Temperature interval of fuse-to-stick operations indicated as an example.

Figure 2 Gathering of 1–3 g mosaic glass *florets* (slices) on a blowpipe: final gather (a) reheated and marvered (b) after eight steps of pickup and reheating in six minutes. Source: Photos Arz.

chunks of “cold” glass stick to the pipe when they were picked up [4]. For gathering, the chunks had to be preheated to about 500 °C to avoid thermal shock. After each gathering, the glass on the blowpipe was shortly reheated to ensure the sticking of the next chunks picked up (Figure 2). At the end of the process, the jumbled mass was heated to higher temperatures to be marvered and shaped into a smooth piece, which could then be blown.

2.2 The Issue of Thermal Expansion

The fundamental glassworking step was annealing, which had to be performed at about 500 °C to prevent the accumulation of internal stress caused by the fictive temperature gradients created through the glass transition (Chapter 3.7). We do not know how and when it was realized that glass had to be cooled down very slowly after shaping, the larger the piece the slower the rates, or when dedicated furnaces or kilns began to be used for annealing. At least three different types of glassblower furnaces are known from the Roman period, one circular and two rectangular, but the function of the latter has not yet been identified clearly. Ancient glassblowers could have used the heat of piles or baskets of hot ashes, olive pits, or the like for annealing, but the cracks observed in many ancient glasses point to often insufficient relaxation of internal stresses. Cracks could also be caused by thermal expansion mismatch in pieces made from two or more glasses of different chemical compositions (Chapter 3.5). In the Late Bronze Age, colorants were usually added by the producers of the raw glass [5]. The composition

changes induced in this way were thus minor so that expansibility conflicts were not likely to create a problem for the brightly colored polychrome objects and vessels fashionable in Western Asia and Egypt, especially in view of the low shaping temperatures [6]. In Mycenaean Greece, where glassworking was also common in this period, the artisans rarely combined different colors within one piece. They used almost exclusively blue glass [1], which was also the preferred color at many Late Bronze-Age working sites in Central Europe and north Italy. Pliny (23/24–79 CE) reports that in his days glass was frequently colored in secondary workshops [7], which would have had the advantage that the glassblowers themselves could control the process and the danger of strain be kept to a minimum [6].

2.3 Molding Processes

Molding was invented long before blowing. In the Late Bronze Age, the most widely used mold materials were stone and especially pottery, which shrank, but less than glass, and then also plaster. The higher the temperature and the longer the cooling, the greater was the danger that the glass would stick to the mold. Although pottery molds without undercuts were reusable, a *separator* substance was needed if the glass was not removed before annealing. Corundum (Al_2O_3) was one substance used for this purpose as indicated by the traces of this highly refractory oxide found in Greek terracotta molds dating from the late fifth or early fourth century BCE [1]. Bone ash, a substance readily available, might have been

Figure 3 Rotary scratches on the interior of a ribbed bowl fragment (Frankfurt/Main, Arch. Mus., inv. α24292) (preserved height 7.2 cm). Source: After [10].

another strong separator [1], as could also have been soot although no trace of it has been found in the rare ancient molds extant [8].

If glass sagged over a convex mold, it had to be lifted off before annealing to avoid cracking through shrinking upon cooling. Plaster molds had several advantages although they could be used only once. Plaster did not undergo volume changes with temperature and its dissolution in water made removal of the mold easy after annealing. In addition, fresh plaster contained some moisture – the so-called crystal water – that evaporated upon contact with the hot glass and acted as a separator ensuring a shiny glass surface [6]. Because of the weakening effect of this water loss, the mold tended to fall apart during or after annealing. A solution to this problem was thus to place the mold in a sturdier container, which provided extra strength during use. Likewise, moist wooden paddles for shaping and plungers for pressing glass created a shiny surface through the evaporation of moisture upon contact with hot glass.

Glass is not a good heat conductor (Chapter 4.5). Whereas cold glass can fracture by thermal shock when touching a glowing-hot blowpipe or pontil, *chill marks*

result from the sudden contact of hot glass with a cold marver or mold. Chill marks appear as wrinkles or ripples on the surface of the glass [9] or as the concentric depressions sometimes seen on the walls of Roman square bottles shaped freehand on a marver. Rotary scratches with a definite beginning and end are often found on shiny surfaces of the inside and bottom of non-blown ancient glass vessels such as Hellenistic sagged vessels and ribbed bowls (Figure 3). The scratches were interpreted as grinding or polishing marks until microphotos revealed that they could be accompanied by shortened *horseshoe chatter marks*, a phenomenon observed after a mishap with hot glass (Figure 4). Because they are found on vessels subjected to a rotary motion either during their shaping or when lifted off the molds, the rotary scratches are now ascribed to friction while the glass was hot, either by protruding particles of ancient tools or molds or to inhomogeneities in the glass [6].

3 Early Shaping Methods

3.1 The Ceramic Connection

Before the invention of blowing in the first century, glassworkers made a limited use of hot glass for both shaping and decoration. Crushed glass and small chunks of raw glass heated at the tip of a handheld tool sufficed for the production of most artifacts. Artisans actually took care not to overheat a piece, which would have been lost if the glass melted. In the Late Bronze Age, the ability to build melting furnaces was likely less problematic than long thought. Whether the Egyptian furnace at Amarna was a primary glassmaking furnace or not, a replica could reach 1150 °C [11]. Hence, difficulties for remelting ingots were not the reason for low-temperature shaping there and in nearby Qantir where primary and secondary workshops were located in proximity [5].

At Amarna and Qantir, glassworking and faience production took place in parallel. The first craftsmen working with true glass had worked previously with faience and other vitreous materials. Consequently, they built on techniques familiar to them. Sintering, for instance, was a ceramic technique to transform a powder into a coherent mass without melting. The raw material was layered into or over a mold, dried, and fired in a kiln. Similarly, fine crushed glass could be layered into or over a mold or core and sintered. Another early technique that had its roots in ceramics was the *pressing* of crushed glass and heat-softened chunks into molds [6]. Extant artifacts show that the glassworkers gradually improved manufacturing techniques, discovered new properties of the material, and invented novel tools and techniques to make use of those properties.

Figure 4 Rotary scratches exhibiting *horseshoe chattermarks* so much shortened that they almost look like vertical lines: a close-up of the fragment in Figure 3 (a) and two micrographs, one of the fragment in Figure 3 (b) and the other of a mishap in hot glass (c) at Schott Glas, Mainz (Germany).

3.2 Core-Forming

The earliest glass vessels were made by core-forming, a generic term for a number of techniques that involved deposition of glass on a rigid core that was subsequently scraped out. In the Late Bronze Age, the deposition of cold pieces of glass was a Western Asiatic specialty.

Vessels known from several sites display colorful figural scenes and zigzag patterns created with short segments of opaque red, yellow, blue, and white canes with circular sections. The individual pegs or canes look as if they had been held together by bitumen, which would have burned off during firing [3]. The vessel's exterior, which was

exposed to the heat, fused better than the interior stuck to the bitumen coating of the core. All these vessels lacked handles and applied decoration, which would have required tooling while the glass was hot [12].

Most Western Asiatic and Egyptian core-formed and rod-formed vessels carry tooled decoration applied to a monochrome underground, the “body” of the vessel [1, 13]. It has been often claimed that the core was immersed into a pot filled with hot molten glass to produce the body. Archeological research and experiments [14, 15] do not support this statement, however, because pots able to withstand hot molten glass are not known at Late Bronze-Age sites [5]. Those used at Amarna and Qantir were much too small to accommodate core-formed vessels that could be from 16 to 26–40 cm in height, like the amphoras found in the tomb of the pharaoh Amenhotep II (r. fifteenth century). Pots for remelting glass actually did not become common until the third century CE, but they still would have been too small. Moreover, the strain induced by a mass of hot molten glass cooling and shrinking around a core would have induced cracks, a phenomenon that has not been attested.

An ancient core-formed bottle from Iraq provided important clues as to manufacturing techniques in the Late Bronze Age [12]. Experiments show that a mold-formed core made from a 10:1 mix of sand and clay, that is pre-fired at about 815 °C, works well [14, 15]. It was mounted on a metal *mandril* (supporting rod), coated with a liquid slip of the same materials, and fired at c. 700 °C after which the core was thoroughly wetted with water to let finely crushed glass stick to it like wet sand. Upon sintering at about 590 °C, the glass glazed over and fused to the core. After further heating up to about 860 °C, successive layers of crushed glass were added by rolling the core back and forth on a flat surface in a way that shaped the vessel and smoothed its wall. This process accounts for the observation that the glass of the bottle from Iraq was layered parallel to the surface of its wall and that bubbles trapped in between these layers were spherical because the glass was not stretched in a particular direction while hot [12]. The handles and decorative trails were made with colored canes prepared independently, while zigzag patterns, festoons, feather patterns, and the like were created with a pointed tool or hook that dragged the threads up and/or down.

Crucial to the success of these experiments was the use of a furnace with a vertical heat chamber, which was open at the top (Figure 5). Because of vertical heat rise, the artisan could manipulate the glass-coated core and the glass canes while controlling the temperature on the relevant side of the piece by a slow rotation of the mandril. In addition, a slit in one side of the opening at the top of the furnace made it easier to work lower down in the heat, for example, when the decorative glass threads were dragged back and forth.

Figure 5 Core-forming furnace open at the top (height 52 cm) as designed and drawn by D. Giberson. Source: After [10].

Although vessels had become much smaller, core-forming enjoyed a prolonged revival from the mid sixth through the end of the first century BCE. [1, 13]. Now, the body was sometimes made from a hot trail of glass wound around the core, with the decorative trails going in the opposite direction [1]. This technique was probably made possible by the discovery that small pieces of pre-heated raw glass could be picked up on the glowing tip of a solid metal rod and sufficiently heated to create a gob of glass from which trails could be wound around the core. The furnace would still have been open at the top. Working directly above, and at times in the heat, the artisan could manipulate core and trail simultaneously, while controlling the temperature of both. The orientation of the heat with respect to the core made it possible to apply an endless thread of glass as observed in the Hellenistic period.

3.3 Casting

In the Late Bronze Age, glassworkers developed the *chip casting* technique reminiscent of faience firing in that its first step was the filling of a mold at room temperature with a finely crushed glass [1]. Upon firing at about 870 °C, more crushed glass was added with a funnel-shaped sprue to fill the mold entirely, as shown by funnel remains on the rim fragments of glass-coloring pots at Qantir [16]. The best evidence for chip casting is provided by the headrests of Tutanchamen (r. fourteenth century). Weighing about 2 kg, the largest one was cast in one piece 17.5 cm high, 28.3 cm wide, and 10 cm deep [17]. The molds would have been made from the same materials as the glass melting

pots used at Qantir, which were lined with a parting layer and specially designed to optimize heat conduction from the outside. A similar parting layer in the molds would have ensured that only a final surface polishing was needed to remove any roughness after annealing [5, 17].

In antiquity, chipcasting was primarily a means of making a single hollow object after a wax model had first been made. Early cast vessels made of transparent colorless glass evoking rock crystal were precious, individual pieces, often imitating the shapes of silver vessels decorated with petals that were convex on the exterior and concave on the interior. Both the wax model and the mold were destroyed in the process: the wax model when the artisan burned it out of the mold in preparation for casting and the mold after the piece was fired. Made of plaster, the mold was broken away to extract the piece.

3.4 Mold Pressing

An important evolution took place when the artisan used a moist wooden plunger to press a gob of glass inserted as hot as possible into a mold to shape at the same time the external and internal surfaces of a vessel, whether plain or decorated with relief. Solid objects, such as amulets, inlays, beads, pendants, and other small artifacts could be pressed in reusable open molds, either with sintered crushed glass or with small pieces of softened glass [1, 13]. Again the technique was closely related to faience. In Bronze Age Egypt, ceramic molds were used, but Mycenaean (Greek) beads and inlays were usually made in steatite molds that could have been used as well for the production of gold ornaments. The numerous techniques used in antiquity for the production of beads and other small objects have been extensively discussed [1, 18] so that they will not be included here.

More important was another form of mold pressing that supplanted the time-consuming casting in the fourth century BCE because the same kind of production could be achieved faster. This was not possible for vessels with a decoration that was convex on the exterior and concave on the interior. However, by far the majority of glass vessels decorated with relief on the exterior now had smooth interiors that presented no obstacle to pressing in concave molds.

One created easily exterior ridges by making a simple groove or drawing a thin line in the interior of the mold [19]. Glass vessels decorated with high relief are commonly assumed to have first been blown and their decoration cut after annealing [19]. But the walls of the ancient vessels are entirely smooth between the elements in high relief and show no signs of grinding or polishing. Hence, the high relief was probably mold-formed [6, 10]. A wax model with the decoration applied to the surface served to create a sturdy plaster mold, which was filled with hot glass. While the mold was turned with some device, a moist wooden

plunger pressed the glass into it. After annealing, the plaster mold fell apart. Simple motifs, ridges, and letters (in reverse) could be engraved directly into the mold.

3.5 Rotary Mold-Pressing

When the mold was put on a turntable or potter's wheel (Figure 6), the combination of vertical pressing and rotary rubbing made pressing at relatively low temperatures possible and ensured a more uniform distribution of the glass for open vessels with a simple cylindrical or outward curving profile. The earliest evidence for the technique comes from Ionia (southwest coastal Turkey) and Greek Macedonia [20] where colorless glass bowls decorated with fine vertical ribs or petals imitating silver work appeared in the middle of the fourth century BCE.

Mold-forming is familiar from the production of mold-made Hellenistic pottery, thought to have been invented in Athens in the last quarter of the third century BCE. The main difference was that potters used molds for mass production, whereas glassworkers could not reuse molds with decoration in relief because they disintegrated and/or had to be broken away from the finished product.

Rotary mold-pressing was also used to *case* glass, i.e. to fuse one layer of glass with another usually of a different color. Cased glass cups, often with a paper-thin, opaque white lining became a specialty in the second quarter of the first century CE. The lining enhanced the transparent colored glass on the exterior. Whereas the layers of colors

Figure 6 Rotary pressing: gob of hot glass pressed with a moist wooden plunger in a turning plaster mold. *Source:* After [10].

in an experimental bowl are thick, mold-pressing made it possible to create an internal lining even thinner than achieved by blowing. In that case, two plungers were needed, one for the external glass of the vessel and another, slightly smaller, for pressing the internal glass [10].

3.6 Rib Making

Toward the beginning of our era, the most popular type of glass vessels were *ribbed* bowls [1, 13, 19]. They are thus regarded as a hallmark for the Julio-Claudian period. No two bowls are exactly the same because irregularities in the length and placement of the ribs show that each one was tooled individually [19]. The ribs were shaped either while a mass of hot viscous glass was sagging over a convex mold placed on a slowly turning turntable (Figure 7) or they were pinched into a pre-formed disk of glass, which was then sagged [21]. Ancient ribbed bowls can be replicated with both techniques. The former yields relatively thick ribs that often curve slightly in one direction and have lopsided profiles like the mass-produced ancient bowls of natural bluish green or more expensive colored glass. The latter yields in contrast thin ribs, usually vertical, like those seen in ancient ribbed bowls executed in expensive luxury glass [21].

A monochrome ribbed bowl could be tooled on a turntable in one or two minutes. No polishing was required because the glass was smooth except for occasional rotary scratches [6, 10]. The rims often show toolmarks from pressing the glass against the mold to stem the flow.

Grinding the exterior of the rim area, which became common in workshops in Italy and northwestern Europe during the first century CE [19], would have required no more than 5 or 10 minutes. Certain mosaic glass ribbed bowls suggest that the distortion of the pattern was not a problem because it made the glass look like a semiprecious stone [1, 19].

3.7 Coiling and Striping: Reticella Vessels

Reticella (network) vessels were made from the eponym *reticella* canes and trails created by application of one or two thin monochrome canes to a transparent, colorless bit of heat-softened glass, which was then twisted and lengthened (Figure 8). For the *spiral* bowls, made from the second century BCE, hot and pliable trails were coiled around a convex mold placed on a turntable (Figure 8). For the *parallel* reticella vessels, [13, 19] produced a little bit later, cane segments were first fused parallel to each other to form a striped disk which was then sagged over a stationary convex mold. In the former, the spiral trail and the bowl were created simultaneously, the trail going from the bottom center toward the rim [1, 10]. The rotary scratches occasionally observed on both types of reticella bowls are an indication that the glass was still hot when it was scratched, either during the turning of the mold or when the vessel was lifted off (Figure 8).

A bowl made from three alternating trails would have required four artisans: three for holding and turning the hot bits of glass of the reticella trails and one for

Figure 7 Making of a ribbed bowl: sagging or flowing down of hot glass over a slowly turning convex mold; rim pressed against the mold, cooling the glass and thus stopping its flow; interstices between the ribs then pressed, pushing up the glass on one side with mold turning. Source: After [10].

Figure 8 Making of spiral *reticella* vessel: drawing of the thread from a rotating conical bit of colorless glass on which two colored canes have been deposited; coiling of the thread around the mold, and final attachment of the rim made of a thicker thread of dark glass (Source: After [2]). Source: After [1].

turning the wheel and pressing the trails against the mold with a moist wooden paddle to obtain smooth walls on either side [6]. No grinding or polishing was possible because the canes were not protected by transparent

colorless glass. A striking feature of spiral reticella bowls is the uninterrupted winding of several-meter length that could be involved, which would have been very difficult to achieve with a stiff thin cane.

3.8 Miscellaneous

Apparently invented in the early second century BCE, a curious technique was used exclusively for the production of small round, lidded boxes known as *Cretan pyxides*. As done by the potter's hands, a moist wooden paddle was applied against a rotating piece of glass in the middle of which a plunger was sunk (Figure 9). This technique did not spread, however, in contrast to *sagging* with which the mass production of vessels began in the first century BCE [1, 13]. With this simple technique, a straight, flat-sided tool pressed a sagging gob or disk of hot viscous glass against a convex mold placed on a turntable, creating at the same time the rim of the bowl. Probably made of baked clay, the mold was reusable, just requiring the finished vessel to be lifted off before annealing and consecutive glass

shrinkage. Mosaic glass bowls [1, 13, 19] required working with a preformed disk composed of mosaic glass slices or *florets* fused together like the parallel striped *reticella* bowls [13, 19]. Before the sagging stage, such disks had to be heated at relatively low temperatures to avoid distortion of the fused patterns during sagging.

Small bulbous bottles predating the discovery of inflation were composed of bands of colored glass or, occasionally, of gold foil sandwiched in between two glass layers [13, 19]. As in mosaic glass bowls, the bands extended through the thickness of the wall continuing on the bottom of the bottles without a seam (Figure 10). The trick could have been to let a preformed glass bowl sag vertically under its own weight over a raised support [6, 10]. Pressing the free-hanging glass toward the stake supporting a plaster mold would have created the neck. Depending on the

shape of the mold, the colorband bottles had bulbous or straight sides.

Glass vessels with angular, often carinated profiles reminiscent of contemporary pottery and metal shapes were popular as fine tableware during the early Roman Empire (c. 25 BCE–50 CE) [13]. They were produced in attractive, usually translucent colors, opaque red, and mosaic glass. But it is not yet known whether they were mold-formed, pressed with a counter mold, and finished by polishing, or rotary pressed.

Far from Italy, seamless glass bangles were a Celtic specialty relying on the enlarging of a bead. The bead was mounted either on a rod-shaped mandril and widened through stretching with a second tool or on a mandril shaped as a cone and widened by centrifugal force.

4 The Slow Blowing Revolution

4.1 A Late Invention

Like other major advances, the discovery that hot air expands heat-softened glass was probably accidental at a time when the wealth of techniques already available was not a strong incentive to invent a completely new

one. Keen observers not only noticed this original feature but were curious enough to take unknowingly advantage of the fact that, in modern physical jargon, molten silicates are Newtonian liquids that can thus deform under very small stresses (Chapter 4.1). At the relevant viscosities, this is why the glassblower could combine the pressure of the breath with gravitational and centrifugal forces to shape glass in especially complex ways with the help of simple tools and the marver [1]. For the earliest blow vessels, the weight was lower than 100 g, with values generally in the lower 7–20 g range.

The earliest archeological evidence for inflation comes from the waste of a Jerusalem workshop active in the mid first BCE or slightly later. The finds include glass tubes pinched closed at their lower end and inflated through their upper end, of which the edge was pulled outward to create a rim (Figure 11) [23]. Glass tubes, made by drawing a hollow bit of hot glass from a metal working rod, were common because chopping them up was a simple way to create beads with a thread hole.

That the earliest inflated glass happened to be a tube was crucial for the development of blowing and the blow-pipe [9]. But more than 100 years of experiments, discoveries, inventions, and improvements separated the first inflated glass tubes from full-fledged Roman glassblowing

Figure 11 Fragments of inflated tubes from a first century BCE Jerusalem workshop: fire-closed inflated bulbous ends, necks, and pulled-out rims. White and black bars: 1 cm. Source: After [22].

in the second half of the first century CE. The introduction of the iron blowpipe, the construction of a new type of glassworking furnace with a horizontal, closed heat chamber, the use of hot molten glass, and the pontil technique for fire-finishing the rim of the vessel were the most important steps in this development [4, 9]. Most, but not all of the tools now taken for granted as integral to the craft were invented during this period.

4.2 Blowing: Pipe and Pontil

As they had done previously with a solid metal rod, the earliest glassblowers throughout the Roman Empire gathered preheated chunks of glass at the tip of the blowpipe, a practice that was still common when blown mosaic glass was produced in the late first to early third centuries (Figure 2) [24]. In the beginning, the glassblowers took care not to let the glass get too hot because it might have dripped off the pipe and be wasted. When they learned how to gather a gob of hot drippy glass, the glassblowers cooled it immediately, either by gentle rotation of the blowpipe or by rolling on the marver. Only after cooling the outer skin could the glass be blown. The rims of early vessels were often ground after annealing or simply left unworked. For finishing the rim, the vessel was held with a clamp, or the artisan blew a bubble of glass on a second blowpipe against the vessel's underside while it was still on the blowpipe [4]. The pipe with the bubble was a precursor of the pontil and the bubble itself became the vessel's base after cracking off.

Invented at an as yet undetermined date in the second half of the first century, the pontil technique was the last major step in the development of glassblowing since it allowed the mouth of a vessel to be shaped while the piece was firmly held by its opposite end (Figure 12). The pontil

was a solid rod. It was attached to the bottom of the vessel with a small wad of hot glass and usually left a scar in the form of gashes or adhesions of glass, which were not removed. The circular form of the earliest scars suggests that the glass remaining on the blowpipe after cracking off the vessel was reheated and the blowpipe itself served as a pontil [4].

4.3 Mold Blowing

To combine blowing with molding was an obvious further step. Three main types of molds were designed, each with its own specific use and purpose. Mold blowing began as a technique to give vessels a surface decoration in relief that could vie with that of chased silver. While free or "offhand" blowing was being perfected in Italy, glassblowers on the Syro-Palestinian coast explored the intricacies of the multipart mold, which determined the size, shape, and decoration of the object [19]. As time went on, the construction became simpler with fewer mold parts. By the second half of the first century, many molds in Italy had just two [9].

Another type of mold, developed in Italy around the middle of the first century, was the box mold, made of stone or terracotta, with four or more smooth walls, that speeded up mass production of prismatic bottles and jars and had the additional economic advantage of not requiring the help of an assistant since the molds did not need to be opened and closed. The vessels' prismatic shapes facilitated packing in wooden boxes, while the base molding enabled recognition of the mold maker, the container, or the content. The realization that mold-blown vessels could be mass produced was probably one of the reasons for the significant drop in production of mold-blown decorated vessels in the third quarter of the first century.

Figure 13 Replica of five-part mold for a beaker, showing mythological scenes. *Source:* Carving and photo by David Hill.

Multipart molds were usually made of terracotta clay and provided with a series of matching bosses and cavities to ensure they fit together as closely as possible (Figure 13). No such ancient mold has been identified beyond doubt, but the number of their parts is revealed by the seams left by the glass that seeped in between [9]. The mold (Figure 14) had to be open to admit the parison, but then it had to be quickly closed and opened again to release the piece without damaging the decoration, which usually had undercuts. The mold was held firm by an assistant while the glass itself was blown rapidly to avoid thermal shock. Necks and rims were usually free blown afterward [8, 9, 19, 25]. The surface of some early Roman mold-blown vessels suggests they were blown into metal molds [8, 9], as was a distinct group of pilgrim vessels decorated with Christian and Jewish symbols produced near Jerusalem in the late sixth and early seventh centuries [9, 19].

Decorative mold blowing experienced a revival in the fourth century with the invention of the *dip* mold to decorate the base and walls of free blown vessels with an attractively ribbed surface pattern [8]. These delicate vessels evoked the luxury of fine-fluted silverware without the odium of mass production, because after exiting the mold, each piece was shaped individually to yield effects comparable to *optic blowing*. The difference was that both the exterior and the interior of the vessel had ribs [19].

Dip molds were always open at the top. They owe their name to the fact that the blower simply dipped the parison on the pipe into them and blew. After lifting the glass out of the mold, the blower could twist the vertical ribs into spirals and even reinsert the piece into the mold to create the basketry patterns seen on some late vessels from the Eastern Mediterranean (Figure 15). Decorated glass cups, tumblers, and bowls blown into shallow dip molds, with a design carved into the bottom, were a specialty of northwest Europe. The central medallion frequently featured a Greek cross or a Christogram surrounded by stylized vines, baskets, birds, wreaths, palm fronds, and trees. One preserved mold is made of limestone. Upon extraction from the mold, the relief decoration was often blurred and farther disfigured by a pontil scar. In spite of the Christian symbolism, most of the vessels were used as secular, domestic tableware [26].

5 Decoration

Shapes and decorative techniques initially imitated contemporary pottery, stone, and metal until it was discovered that glass made new types of decoration possible through controlled manipulation and/or expansion of ornaments applied to the surface, and the use of colored

glass. *Hot* decorative techniques involved the application of trails and bits of glass to the vessels' wall as well as pinching, nicking, poking, and twisting the applied ornament or even the wall itself. Colored trails and crushed glass applied before blowing could be manipulated to create marbled patterns that imitated precious stone, whereas threads in relief or prefabricated designs made of trails nicked with a specialized tool were welded after full inflation to prevent them from melting back into the wall. Early on, the *zarte Rippenschale* combined spirally wound trails with thin ribs pinched before full inflation of the parison.

Cold decoration involved faceting, engraving, and painting. Either by hand or with the aid of a rotary tool, grinding and polishing with water and an abrasive were the earliest methods used to modify glass surfaces as shown by the linear patterns present on the undersides of fourth century BCE colorless glass bowls imitating the decoration of contemporary metal vessels. Many sagged and ribbed bowls were decorated on the interior, below the rim, and/or lower down on the body, with horizontal grooves which looked like molded ridges when seen through the glass walls. The exterior of the rims of ribbed bowls was frequently ground to remove toolmarks.

After the invention of glassblowing, cut decoration became common, especially on vessels and objects made of colorless glass. Its practice was tricky, however, if the glass had not been properly annealed. Facet cutting was

an Italian innovation, which predated the eruption of Vesuvius in 79. Round, oval, and non-touching deep facets were the hallmark of early Roman cast colorless fine dishes and plates of the first and the early second centuries. Their optical illusion of evoking raised knobs in transmitted light was probably discovered when the interior of clear vessels was decorated with horizontal grooves that looked like moldings. In contrast, close-set, shallow circular or oval facets cut into the exterior surface of glass beakers, cups, and bowls were meant to be seen with reflected light, each facet reflecting it differently to create a dazzling shimmer. In the second century, cutters began to arrange the facets in horizontal zones divided by linear grooves, which was often less labor intensive than covering the entire surface with facets and facilitated the creation of more complex designs. Like facets, engraving showed up best on colorless, transparent pieces so that the technique was most common when this type of glass was in fashion. Some vessels were cut or abraded by a stone or a fine metal wheel whereas others were incised free hand, probably with a flint or possibly a diamond point. Many engravers used more than one technique on a single vessel.

Sophisticated cold work, such as painting and figural engraving, probably was executed by specialized artisans. But very little is known about their relationships with the glassblowers, the organization of the trade in blanks, or the role of patrons. As was true in other trades, glass engravers probably relied on model books. Differences in cutting techniques and cutting styles suggest that glass engravers had a firsthand knowledge of three-dimensional models, perhaps through plaster casts. Free-hand engraving with linear shading imitated the darkened outlines of paintings and mosaics. Dulled, abraded areas created color effects and the cutting of glass in *intaglio* recalled the raised relief of metal. Egypt, Rome, and the Rhineland were home to some of the most prestigious workshops. Reflecting the Christianization of the empire, several workshops added Christian subjects to their repertoires in the second quarter of the fourth century.

6 Special Techniques

6.1 Hellenistic and Roman Gold Glass

The most luxurious glasses of antiquity have long puzzled researchers. The earliest are double-walled gold glass vessels first made in the Hellenistic period and again in the “Roman” fourth century, but in a totally different way. In the former (Figure 16), the technique for cutting and applying the floral gold foil decoration closely resembles the Japanese *kirikane*, which is eminently appropriate for ornamental motifs [27]. The elegant floral patterns

sandwiched between two close-fitting colorless glass bowls were remarkable for their lack of cracks, an indication that the gold foil was not subjected to excessive heat. If the two glass bowls were formed by rotary pressing, three moist wooden plungers would have been needed: two larger ones of the same size for the outer bowl and the gold foil pattern, and a third, slightly smaller one, for the inner bowl (Figure 17) [10].

The late Roman gold glasses served a different purpose. They were not extravagant gifts for the happy few, but often became grave markers in catacombs after having been crudely chipped to shape. They depicted Christian, Jewish, pagan and mythological themes, married couples, portraits, animals and secular events like horse races, and often bear Latin mottos wishing their owners to prosper (*vivere*) or drink well (*bibere*). In most designs and mottos, the gold foil of the figural scene and inscriptions was applied onto the surface of the cold glass with water or a light adhesive [19]. The bowl and the foot were blown separately. To prevent thermal shock, the part of the bowl bearing the decoration needed to be reheated before the glassblower blew and shaped a second bubble (the bowl or the foot) and fused it hot to the part bearing the decoration. As a result, the gold foil was always full of tiny crisscross cracks.

6.2 Cameo Glass

As exemplified by the famous Portland vase in the British Museum (Figure 18), cameo vessels were usually blue and decorated with opaque white relief. It is generally claimed

Figure 17 Three-step making of *gold glass*: pressing of the gob of the outer bowl in the mold, deposition of the gold-foil pattern adhering to a plunger of the same size, and pressing of the gob of the inner bowl with a slightly smaller plunger. *Source:* After [10].

Figure 18 Cameo glass: the Portland vase (height 24.5 cm, maximum body diameter 17.7 cm, weight 1.306 kg). Late first century BCE. *Source:* British Museum 1945,0927.1, © The Trustees of the British Museum.

that the molded white decoration was carved from bicolored blanks [28]. Some of these vessels are very large and heavy, however, and date from the very beginning of blowing when the new vessels were tiny and light weight. In addition, the pontil technique, which played a basic role in the production of blown blanks, had not yet been invented and the cross-cutting shears needed for creating the rims were also unknown. The presence of rotary scratches and the fact that the decorative relief never extends beyond the shoulders of Cameo vessels rather point to a first step of rotary mold pressing in a decorated plaster mold (Figure 19). First, the cavities for the decoration were filled with powdered opaque white glass. A drop of water held the powder together until it was dried. Then the hot blue glass was rotary pressed into the mold, melting with its heat the white glass. For a higher relief, powdered glass could be sintered in the plaster mold before rotary pressing of the hot blue glass.

6.3 Cage Cups

The *diatrete* (cage cups) are probably the most outstanding pieces of glass ever produced (Figure 20). Their decoration consisted of figural or network patterns. The earliest true cage cup is figural and dates from the late third century [29], preceding the network cage cups made

Figure 19 Two step-making of a cameo glass: model of wax or clay serving for the hollowed out interior decoration of a plaster mold, whose cavities are then filled with powdered white glass before pressing of hot blue glass into the mold with a plunger. Source: After [10].

Figure 20 Diatrete, Cage cup (preserved height 12.1 cm, rim diameter 10.1 cm). Köln, Römisch-Germanisches Museum 60.1. Source: Photo Cornelius Steckner, courtesy the Museum.

from the fourth century. Similarities with high-relief glass suggest that the earliest precursors might have been produced in a workshop specialized in high relief. The figures are often undercut so that many details stand free from the background [29], in imitation of contemporary *repoussé* silver vessels.

Carving of thick-walled blanks would have been a possibility because the water mill, indispensable for supplying energy to the cutting tools, had become common throughout the Roman Empire by the fourth century [22]. However, in addition to extremely severe breakage and cracking problems, the time spent on cutting and polishing would have been considerable. A much quicker and safer alternative [6, 30] is to assume that one made cage cups by pressing a double-walled blank on a turning wheel (Figure 21). After pressing the first gob of hot molten glass into the mold (the future cage), the glassblower inserted a smaller, perforated plaster mold into the hot glass and used a smaller plunger to press a second gob of hot glass into the mold to form the main body and to force at the same time some glass through the perforations. The tiny bridges connecting the cage to the inside bowl thus became integral parts of the main body as actually observed, although occasionally the two glasses meet somewhere along the bridge if some of the glass from the outer bowl (the future cage) was forced back into the perforations when the inside bowl was pressed.

Figure 21 Four-step making of a double-walled blank for subsequent cutting of a diatrete: pressing of a first gob for the outer bowl of the network cage, insertion of a perforated plaster mold, pressing of a second gob for the inner cup and the bridges through the plaster mold, and creation of a ridge while the rim is shaped. Cross section of the double-walled blank with the perforated plaster cup still inside also shown. *Source:* After [6].

7 Secondary Glassworking

7.1 Workshops

In antiquity, glass *making* and *working* remained two separate crafts, each with its own pyrotechnology and ancillary techniques. Unlike primary production (Chapter 10.3), the shaping of glass was not bound to a specific location. Secondary workshops could be located near primary workshops, as in Israel and Egypt, but all they needed was a supply of raw glass which could come from afar (Chapter 10.3). How this trade was organized is not clear, but ingots, chunks, and even cullet found in ancient shipwrecks point to transport by sea, frequently as inexpensive ballast. Textual evidence indicates that recycling became an important source of supplies from about 70 CE on [4, 31].

Secondary glass workshops were located either on the edge of town in northwest Europe (to minimize the risk of fire) or more centrally in the Eastern Mediterranean. At Bet She'an (Israel), a downtown workshop destroyed by a sixth to early seventh century earthquake had a courtyard and two connecting rooms showing traces of shelves for storing glass vessels [32]. Most of the vessels were kept in the front room, where the furnace was located next to the wall of the doorway, surrounded by moils or crack-offs from the blowpipe, knock-offs from the pontil, and glass drops. On either side of the furnace, blown vessels and olive pits (known for their heat-storing properties) were found in heaps of black ash, which probably served as rudimentary annealing lehrs. Piles of glass chunks lay ready for use. The storeroom contained additional shelves of vessels, sacks filled with cullet, and a large jar full of chunks of raw glass.

7.2 Furnaces

Some Roman oil lamps depict a worker blowing a tall-necked bottle while sitting on a low stool in front of a marver depicted as a small ledge protruding from the furnace (Figure 2, Chapter 10.4). The piece attached to the blowpipe could be entered horizontally into the furnace's upper compartment through the working port at the center. The lower compartment served for stoking. The rectangular blocks on the floor in front of the furnace were probably blocks of raw glass waiting to be used, but what the squatting man was doing on the left is unclear.

With respect to the core-forming furnace, the most significant change was the closed, horizontal heat chamber. It allowed not only higher temperatures to be reached but also ensured that the glass heated evenly on all sides, which was crucial for expanding evenly during inflation. The new glassblower's furnace was thus a revolutionary invention. It had one major disadvantage, however, which persists today: because the artisan cannot shape the glass and simultaneously control its temperature, all the shaping has to be done outside the furnace in between successive reheating steps. The basic distinction made between *short* and *long* glasses (Chapter 4.1) is thus a direct consequence of the invention of the glassblower furnace.

The remains of the lower structures of these furnaces have been found all over Europe. The majority are circular, with an inner diameter of about 45–70 cm. Pots for remelting raw glass were rare before the third century, but common later on. Tank furnaces have been assumed to exist as early as the mid first century because glass dripings were observed on their floors, but no pots were found [33]. It has been argued, however, that tank furnaces did not become common until the third quarter

of the first century, when polychrome vessels went out of fashion and blowers began to use mostly natural bluish green glass [34]. This meant that one color of molten hot glass sufficed. As observed at other mid first century furnaces [35], the drippings on the floor resulted from small chunks of raw glass that got too hot and melted when they were picked up on the tip of the blowpipe.

7.3 Tools

Neither the commonly held opinion that ancient blowpipes were made of iron from the beginning, nor the hypothesis that ceramic blowpipes were used at an intermediate stage [1] can be proved or disproved at this moment. The earliest evidence for the use of iron blowpipes is the presence of oxidized iron in mid first century waste glass, originating from the *crack-offs* remaining attached to the blowpipe after separation of a completed vessel [35].

In addition to the blowpipe and the pontil, the U-shaped iron shears with parallel blades were the most important glassblower's tool of antiquity. Originally a Celtic invention, this *forfex* was the universal cutting tool of the Greco-Roman world, thanks to the springy blades that opened automatically when not pressed together (Figure 2, Chapter 10.9). The tool could not cut hot viscous glass, however, which is why Roman glassblowers usually began the handle of a vessel at the shoulder, pulled the glass up, and attached it at the upper end where they drew the extra glass out thin and snapped it off. Often they folded the extra glass back and forth to create interesting folds and spurs at the upper end of the handle [19]. For most ancient glassblowing techniques, these simple iron tools sufficed along with a wooden board for shaping and a wooden stick for widening rims. An interesting feature seen on many Roman blown vessels is the fire-polished rim that resulted from the wooden stick catching fire through contact with the hot glass. When shaping was completed, a gentle tap on the pontil let the piece slide onto a wedge-shaped branch to be deposited for annealing.

7.4 Blowers

Unlike pottery, glassblowing did not develop into a large-scale enterprise in antiquity. The Roman glassblower furnace was small, imposing physical restrictions on the number of persons who could work simultaneously [4, 34, 35]. Nevertheless, a glassblower could have averaged 100 vessels per day or 330 000 in 30 years. That such a long period of activity may have been possible is

suggested by the tombstone of the *opifex artis vitriae* Julius Alexsander who died in Lyons at age 75 [4, 31].

Little is known about the financial and social position of glassblowers although quite a few names are known. Ennion, who specialized in fine mold-blown tableware, stood out above all others in the first century eastern Mediterranean. The addition of *the Cypriot* or *from Sidon* in signatures found on mold- and free blown tableware, respectively [9, 31], suggests that others too moved through the Roman Empire as did Julius Alexsander, who was born in Africa. As for the aforementioned Roman oil lamps (Chapter 10.7, Figure 4), the names of the glassblowers added on one of them may indicate that they were Athenian *liberti* (freemen) working in Italy [4].

According to papyri, legal documents and epigraphic sources, glassworkers in Egypt were regarded as a group for tax purposes in the early first century and as a guild in the fourth [4, 31]. Elsewhere, artisans appear to have been independent entrepreneurs probably leasing their facilities as did potters [4, 31]. If clearance on exit had been a general condition in leases, that would explain the existence of large deposits of waste glass and cullet buried in pits as found in glass workshops at Saintes (France), London, and Nijmegen (The Netherlands) [31].

In antiquity, women were active in beadmaking and glassblowing. Also known as Didyme, a Sarapodora is mentioned in a mid third century contract along with two male glassworkers from Koptos [36]. Female names are also found in basemarks on the undersides of square bottles [37]. Sentia Secunda (late first to early second centuries) added the information that she made VITR (*vitrum* or *vitra*) glass (or glass vessels) at Aquileia (Italy).

The price of glass varied depending on the kind of production. Raw glass and smooth (i.e. undecorated) glass vessels were sold by the pound. According to the Edict of Maximum Prices issued in 301 by the emperor Diocletian (r. 284–305), the 25 *denarii* daily wage of an unskilled laborer would have bought one or two vessels of *Judaeian* (naturally colored bluish green) glass or one vessel of *Alexandrian* (colorless) glass of average size. Even though these prices were 10–20 times higher than that of an equivalent pottery vessel, they were probably lower than the production cost of Judaeian glass [4, 38]. As for window glass (Chapter 10.8), the maximum price was 8 or 6 *denarii* per pound depending on quality. A 25 × 25 cm window pane would have weighed about 2.2 Roman pounds and cost 17.6 or 13.2 *denarii* for the best and lower qualities, respectively [38]. As the main function of window panes was to bring in light without losing warmth [39], glazing did not require the same quality as vessels, which is why the former glass was much less expensive than the latter [38].

8 A Short Retrospective Overview

8.1 The Spread of Glass

Vitreous materials had been around for more than a millennium before true glass was made on a regular basis, from c. 1550 BCE onward (Chapter 10.2). Because the new material did not prove indispensable for any specific function, it owed its initial success to the brightness of its rich colors, which surpassed those of natural stones and the glow of faience. Glass was used first as beads, jewelry, and decorative inlays in furniture, boxes, and coffins, and even in architectural context as wall decoration [13], then as colorful core-formed vessels. As an intermediate production step, colorless and natural bluish green colored glass was not valued as such [5].

Clear colorless glass, purposely decolorized with antimony (and in later periods often with manganese), made its first appearance at Gordion (Phrygia) in the eighth to seventh centuries BCE. Wide, shallow bowls were decorated with a petal motif that was convex on the exterior and concave on the interior in imitation of metal vessels. The fashion was revived in the late fifth to fourth centuries BCE with bowls that were usually smooth on the interior. The glass itself obviously imitated rock crystal, with which such shapes would have been difficult to create because of polishing difficulties and of the risk of disfigurement or breakage caused by a small mishap.

The ease of shaping glass led to several new applications of transparent glass in the Roman period. Again its acceptance began much earlier as a *thing of beauty* reserved at first for temples as dedications to the gods and for luxury items such as jewelry. From the mid fourth century BCE colorless glass vessels began to grace the tables of the wealthy [20]. In Greece, the optic qualities of clear colorless glass were a source of fascination from the moment it became available. In addition, transparent glass played a role in the construction of mechanical devices and gadgets and especially in the beginnings of optical studies (Chapter 10.10).

It is usually thought that the invention of glassblowing revolutionized the ancient glass industry because vessels could be made much faster. However, it was taking longer to blow a ribbed bowl than to make one by tooling on a turntable. The first mass-produced glass vessels, Hellenistic grooved and sagged bowls, predated the first blown vessels, as did ribbed bowls, which were still being sold in Herculaneum at the time of the Vesuvius eruption in 79 when blown drinking vessels had ousted pottery thanks to their already well-known advantages.

Blowing enlarged the existing repertoire of vessels with a wide range of shapes so that the use of glass in households increased greatly during the first century CE. Much

of it was blown, but blown luxury wares were nonetheless rare before the introduction of the pontil. Glass lamps became common from the fourth century onward [4] especially in Italy and the Eastern Mediterranean. However, it was for windows that transparent glass had the most impact in antiquity (Chapters 10.3 and 10.8), and it was during the Roman Empire that wall and floor mosaics made of colored glass cubes became common in private villas and public buildings.

8.2 The Slow Rise of Glass Blowing

After the discovery of inflation in the eastern Mediterranean, it took at least one century until the novel blowing technique spread widely, even to western Europe, after it had been perfected in Italy. As usual, older materials, techniques, and concepts survived for a considerable time. The first successful innovation in glassworking had been core-forming, which transformed a ceramic technology into a widely accepted technique of glassworking. Primarily (but not exclusively) a means for the production of attractively colored bottles, core-forming was so successful that it remained in use for 1500 years. The earliest blown vessels were small glass bottles, commonly called *unguentaria* or *balsamaria*. By far the easiest and most simple shape to produce with the novel technique, many bottles were blown in attractive transparent colors. Even more bottles were blown from natural bluish green glass, which was less expensive. These bottles were much lighter than their core-formed equivalents, not a negligible factor in an economy where glass vessels were sold by weight. In addition, blowing was considerably faster than forming around a core that had to be scraped out laboriously and left an uneven surface that contaminated the interior and hampered reuse. The invention of glassblowing caused the death of core-forming.

The new blown bottles fulfilled a real need as containers for medicinal preparations. Thousands of *unguentaria* have come to light all over the Roman Empire in civil and funerary contexts. Glassblowers soon enlarged their repertoire with bottles, jugs, and jars, which were difficult to produce by rotary pressing because the diameters of their neck and/or rim were smaller than their maximum diameters. Rotary-mold pressing was nonetheless the most serious rival of glassblowing. Like core-forming, it stemmed from ceramic technology, but it gave rise to many other techniques predating blowing and took great advantage of the properties of plaster for making molds. Thus, innovation was slow with respect to fine glass tableware, especially for open shapes with a rim diameter equal to or larger than the maximum diameter.

Throughout the first and well into the second century, rotary pressing and related older techniques remained important production methods next to blowing. Eventually, glassblowing became dominant for all vessel glass, but rotary pressing did not disappear entirely.

The development of glassblowing was hindered by the slow acceptance of the pontil technique. Many workers apparently did not trust the transfer from blowpipe to pontil when blowing large heavy pieces such as cremation urns with massive, decorative glass handles. The absence of pontil scars suggests that the glassblowers reverted to earlier techniques such as the use of a clamp to hold the vessel.

The three types of molds invented in antiquity each had a different impact and different history with respect to innovation. Decorative mold-blowing with the aid of multipart molds began in the Eastern Mediterranean during the first quarter of the first century CE as a way to emulate contemporary silver vessels decorated with *repoussé* relief [9, 40]. The technique may have been introduced into Italy in the early first century. However, unlike the small free-blown bottles, which were an immediate success, vessels blown into multipart decorated molds did not thrive in the West before the mid first century [41]. After the technique gained a foothold in Italy, the construction of the molds was simplified. Many pieces were blown into two-part molds. The introduction of box molds for the mass production of prismatic vessels caused general recognition that mold-blown decorated vessels were not individually crafted. As a result, decorative mold-blowing fell out of favor in the West [9, 40]. The box mold for blowing prismatic bottles and jars was invented in Italy around the mid first century CE or slightly later. It was an immediate success. In the eastern part of the Roman Empire, the use of box molds was never as universal as in the west.

In the late third or fourth century, glassblowers invented a technique for blowing window glass, the cylinder technique [39], which would eventually oust cast flat glass of the matt/glossy type and remain in use for the production of flat glass until the twentieth century (Chapter 10.8). In this domain, too, innovation was slow. In the east, the older technique persisted in use for some time.

The fourth century was actually an innovative period in the history of glassblowing [9]. Syrian blowers began to expand geometric surface motifs created in multipart molds by continuing to blow after exiting the mold. Expanded concentric circles were the commonest motif. Although this technique remained a regional curiosity, it pointed the way to a novel use of decorative molds that would dominate mold-blowing for all times to come, namely, the dip mold. Syro-Palestinian glassblowers used these molds to create bowls with barely expanded

honeycomb patterns, which were appreciated east and west. The real success story, however, was the vertically ribbed or fluted dip mold. Easy to make and easy to use it enabled the glassblower to produce a large variety of expanded vertical and spiral rib patterns in imitation of contemporary silverware.

9 Perspectives

The scenario of a gradual development and anchoring of ancient glassworking techniques based on rotary mold-pressing makes sense from a historical and technological viewpoint. Although experiments have demonstrated the feasibility of the proposed reconstructions, dissent among specialists is polarizing the community of glass researchers in many fields of research from art historians and archeologists to chemists, laboratory scientists, conservators, and glassblowers. With Lierke's theoretical reconstruction drawings in hand [6, 10], a new generation of glassblowers can begin to experiment and/or attempt to produce reliable replicas of ancient glass vessels. For the shaping of vessels with carinated profiles, made perhaps on a raised support, the lack of an appropriate furnace for working above and in the heat may be an issue that needs first to be resolved. The advantages and disadvantages of working glass with such furnaces have yet to be fully explored. The price of gold foil sufficiently thick for experiments to replicate Hellenistic gold glass may be an obstacle of a more prosaic kind.

Two quite different projects will finally be mentioned to illustrate the diversity of approaches followed to understand better ancient processes. The first aims at making basic information on important pieces as widely available as possible through an open-access database set up at the Römisch-Germanisches Zentralmuseum in Mainz (Germany). Its goal is to document Roman cage-cups thoroughly through high-quality photographs of both vessel and surface [42]. Hopefully, the documentation will include microphotos of the reverse of the cage and the interior wall of the cup where details such as shortened horseshoe chattermarks suggesting double-walled pressing might be detected. Launched at the initiative of the Australian National University at Canberra, the second project highlights the use of state-of-the-art techniques applied in industrial or academic glass studies (Chapters 2.1 and 2.2). Through high-resolution X-ray scanner tomography combined with a visualizing software program, the important question addressed in this case is the production of cameo-glass vessels and, in particular, the nature of the interface formed between the white and the blue glasses during the shaping process.

10.6

Glazes and Enamels

Philippe Colomban

MONARIS, UMR CNRS 8233, Sorbonne Université, Paris, France

1 Introduction

Glass has long been highly valued in the form of thin layers termed *enamel* or *glaze* depending on whether the substrate on which it is deposited is smooth (e.g. metal and glass) or porous (e.g. porcelain). From Egypt, Phoenicia, and Mesopotamia to the Indus Valley, glazed artifacts date back to about 2000–1500 BCE [1]. There is actually evidence that bulk glass was a by-product of glazes, once the great aesthetic and practical value of the new material had been acknowledged in the Middle East (Chapter 10.2). Such coatings were used not only for decoration purposes (Figure 1) but also for tightening a porous body and hardening its surface, which made, for instance, possible to keep safely liquids or other substances in large pottery vessels. In the Western world, the first enamels date back to at least 1500 BCE in Cyprus [2] whereas an older written mention of an enameled shield is found in the *Iliad* (eighth BCE). From diverse areas, famous artifacts include an eleventh century BCE enameled bronze wine ladle from the early Western Zhou dynasty (British Museum) or numerous Celtic enamels on brass, bronze, gold, and iron made from at least the fourth BCE with blue, red, green, yellow, and black hues [3]. As to *millefiori* (1000 flowers, in Italian) enamels, they appeared in Ireland during the seventh century CE.

Since then, a great many new applications have been designed, ranging from porcelain or glass isolators coated with iron oxide-rich enamels to improve the electrical insulation of wire supports in wet atmospheres [4] to

the development of advanced ceramics such as particular dielectric passive components (e.g. capacitors, substrates, sockets) that are at the roots of the development of microprocessors and computers. Glazes are also deposited on alumina electronic substrates to be used in standard or harsh conditions [4] whereas, following a tradition originating in the glazes deposited on stone in ancient Egypt [1], enameled lava remains used in contemporary building décor.

Regardless of their functions and of the possibly complex shapes of their substrates, the deposited glass layers must not exhibit any puddle but have a constant thickness. Hence, it is obvious that enameling and glazing technologies involve much more than the preparation and firing of glass compositions. Without trying to deal with all varieties of enamels and glazes (Figures 1 and 2), this chapter will review their current preparation and the technical constraints exerted in particular by thermal expansion matching, describe the most pertinent innovations regarding composition and color, and finally present an overview of the history of enamels and glazes.

In preamble, some definitions are in order: *stoneware* designates nonporous pottery or ceramics fired at temperatures higher than 1200 °C; *fritware*, pottery in which some ground glass has been mixed with the starting clay and sand material to promote partial melting upon firing to cement the grains with the molten frit; *porcelain*, various kinds of white wares that share a common vitreous surface and a nonporous body as first made from 3000 to 1500 BCE during the Chinese Shang and Shang-Zhou dynasties (in the form of protoporcelains, which were already fired up to about 1200–1250 °C) [5]; *celadon*, a green Chinese porcelain as named in France in the seventeenth century; and *cloisonné* and *champlevé*, enamels prepared with two different kinds of techniques.

F. Böttger, Meissen, early eighteenth century, Sèvres Cité de la Céramique Coll.); largest dimension ~20 cm, except (a), (b) (~12 cm) and (f) (~150 cm). Source: Photos Ph. Colomaban.

2 Preparation and Thermal Constraints

Coatings, in general, are made from either glass precursors through in situ reaction and melting or with ready-to-use glass frits. An aqueous slurry is prepared from these materials if the substrate is an unfired or a porous pottery. The slurry is deposited by immersion of the object or painting with a brush or spray dried. The slurry must have the right viscosity, thixotropy, etc., which are optimized with specific additional ingredients such as clays, kaolin, or polymers and glues. If the substrate is not porous, water is replaced with organic solvents/media and glues or similar additives are incorporated. The coated items are then heated to form the glass coating and to develop a specific color and/or gloss.

The coating thickness ranges from a few tenths of microns in *salted* stoneware to a few millimeters in *celadon* and *cloisonnés*. The coating must readily melt upon firing to yield a nice gloss and join smoothly with the substrate, which requires the precursor mixture to consist of

a fine powder. Along with firing, grinding is the most energy-intensive operation in the *Arts du Feu*, which might be why mechanized grinding techniques were developed only in the Middle-Ages with water mill energy. To get fine powders, ancient craftsmen thus relied instead on the firing of plants (ashes), shells and calcareous stone (chalk), bones (ashes), and flint pebbles (silica) together with water washing to eliminate impurities. In this way, they sometimes achieved directly the right composition (Figure 1e) [6].

However, craftsmen have long known that composition is not the sole parameter that governs final quality [6–11]. For a given composition, the glaze can be matt or glossy, well coated (Figure 1c), or crawled (Figure 3c) depending on grinding time. The glaze ingredients used to be ground in a mortar or in a rotating barrel of water containing flint or quartz pebbles (now steel, alumina, or zirconia balls depending on glaze composition). Upon firing, the reaction rate increases with the initial compaction of the deposit and it also depends on temperature, duration, heating rate, particle size, volatile content, and on the reducing or oxidizing nature of the gas atmosphere.

Figure 3 Firing defects on glazes and enamels. (a) Celadon cracked glaze (nineteenth century, Qing Dynasty, Private Coll., $\sim 5 \times 8 \text{ cm}^2$); (b) high-quality Mamluk enameled glass bottle (diameter: $\sim 15 \text{ cm}$), exhibiting a high-quality glossy enamel and (c) Mamluk enameled mosque lamp (diameter: $\sim 30 \text{ cm}$), where the glaze has failed to adhere to or wet the body on firing (crawling) (fourteenth century, Louvre Museum Coll.); (d) *Cuerda seca*-like technique: a line hinders the glaze to go out of the defined area (fifteenth century, Ottoman Empire, Private Coll., $\sim 4 \times 9 \text{ cm}^2$); (e) micro-crazed red glaze of a gilded Meissen Bottger stoneware (Sèvres Cité de la Céramique Coll., $\sim 4 \times 6 \text{ cm}^2$). Source: Photos Ph. Colomban.

Figure 4 Control of the glaze quality: comparison between the thermal expansion of a quartz-rich ceramic body (solid line, α - β phase transition) and a glaze (dashed line; T_g : glass transition temperature; s.p.: softening point).

Because sintering is driven by atomic diffusion, longer heating times have similar effects as temperature increases or grain size decreases.

Controlling the contact angle between the melted coating and its substrate is mandatory to ensure complete wetting and also to keep the thickness constant. Bonding between the substrate and the coating is also very important. For metal substrates, a ground or under coat is generally needed to ensure adherence and accommodate the thermal expansion mismatch between upper coating and substrate [4]. Cobalt and nickel oxides were the best materials in this respect, followed by cupric, manganese, and iron oxides. Glazes for decorative purpose were then applied on the ground coat.

Coatings widely differ in composition because of the thermal-expansion match that must be achieved with a great many different substrates during the firing and cooling operations (Figure 4). Two different techniques are distinguished in this respect. With the *Grand Feu* (Great Fire), for instance, used to make porcelain, the coating and its substrate are simultaneously fired at temperatures ranging from 1200 to 1400 °C. With *Petit Feu* (Small fire), Muffle fire, or *mina'i* (in Iran), lower temperatures of 600–1000 °C suffice because the substrate has been separately fired once or twice at higher temperatures [10, 11].

In practice, the thermal expansion coefficients of metals range from 100 to $220 \times 10^{-7} \text{ K}^{-1}$ (steel, 90–180; gold, 140; brass/bronze/copper, 180–160; silver, 195; aluminum, $220 \times 10^{-7} \text{ K}^{-1}$). These coefficients are generally lower than $100 \times 10^{-7} \text{ K}^{-1}$ for ceramics (amorphous silica, 1–0; SiC, 35; mullite, 50; porcelain, 65; alumina, 75; zirconia, $105 \times 10^{-7} \text{ K}^{-1}$) and can even be negative for β spodumene/eucryptite (-10 to $-5 \times 10^{-7} \text{ K}^{-1}$, cf. Chapter 7.11).

A further complexity results from the α - β phase transition of quartz, which causes a highly anomalous expansion near 565 °C (Figure 4) for quartz-rich raw materials. As for silicate glasses, their thermal expansion coefficient increases from 30 to $80 \times 10^{-7} \text{ K}^{-1}$ from borosilicates to lead-based materials, and decrease when SiO_2 , B_2O_3 , CaO , MgO , or ZnO are substituted for Na_2O and K_2O [4, 7]. Although thermal expansion of solids is a complex phenomenon determined at the atomic level by the number of bonds per unit volume and their anharmonicity, it has long been accounted empirically with coefficients first assigned to the constituting oxides by ceramist Hermann Seger (1839–1893). Optimized calculators are now available [12].

Another important property is tensile stress. As usual, it is much smaller on tension than on compression for silicate glasses. Because of its thinness, a coating should not be put under tension but gently compressed by the substrate. The slow expansion experienced by porous ceramics with time if exposed to humidity must also be accounted for. Upon cooling below the softening point, i.e. the temperature at which the coating layer sticks on the substrate (Figure 4), the contraction of the glass coating is monitored by the thermal expansion mismatch [4]. To result in a compressive stress, the thermal expansion of the glass should be lower than that of the substrate. On the contrary, a glaze cracks when the substrate expansion is too low (Figure 3) whereas too high a compressive strength causes peeling.

The most common defects of coatings are volume bubbles, craters, and pinholes induced by gas formation, generally from the body-interface reaction when glaze and body are fired together. However, small, micron-sized bubbles are specially developed in *celadon* (Figure 3a) and opal glazes [9, 10, 13] for opacification or aesthetic effects.

3 Composition and Microstructure

3.1 Pottery Glaze

The raw materials actually used are not oxides, but mineral substances such as stones: clays, feldspars, talc, quartz, flint, or carbonates, the components to which craftsmen refer [4, 6–9, 14]. Because the compositions of these natural substances are highly variable, even within a given quarry, craftsmen mix raw materials from different places or, better, from different origins to average out differences and limit chemical fluctuations. When adjustments could not be made in the past in response to composition changes, then the quality of the production was decreasing and the factory might even disappear.

Like materials scientists, archeologists and art historians usually report glaze and enamel compositions in

Table 1 Modern porcelain glaze compositions expressed in terms of either oxide or raw materials (wt %, after [16]).

Raw materials	Oxide	NG6 glaze	NG33 glaze
	SiO ₂	63.16	73.87
	Al ₂ O ₃	17.87	14.31
	CaO	11.46	4.95
	K ₂ O	5.72	4.85
	Na ₂ O	1.37	1.16
	Fe ₂ O ₃	0.19	0.14
	TiO ₂	0.05	0.03
	MgO	0.19	0.69
Standard kaolin (ECC) ^a		8.70	7.85
Calcined kaolin (Dorkamul) ^b		13.16	8.75
Quartz (Norquartz 45) ^c		6.89	33.35
Feldspar (Norflux 45) ^c		45.67	38.45
Wollastonite FW325 (Partek) ^d		25.58	8.90
Dolomite (Microdol 1) ^e		—	2.70

terms of oxides or elements as determined from chemical analysis (Chapter 5.1, [15–17]). Potters and enamelers put the emphasis instead on raw materials, which actually determine the actual firing process relevant to their batch (Table 1). They do it by following another procedure designed by Seger who distinguished acid [SiO₂], amphoteric [Al₂O₃], and basic [flux: CaO, Na₂O, K₂O, and MgO] oxides [4, 6, 14]. The temperature, at which a liquid phase forms, a basic parameter for the reaction/bonding of the coating with the substrate, is then determined more by the particular raw materials used than by the mean chemical composition. Because the advancement of reactions (through atomic diffusion) depend on both temperature and time, Seger in addition designed reference cones made up of specific mixtures, which deforms and melts according to given controlled firing conditions (temperature and heating rate) in the wide temperature interval 500–1520 °C [12]. The interest of the procedure is apparent in Table 2 where firing temperatures range from ~600 (Cone 022) to ~1430 °C (Cone 15).

Compounds such as lead oxide are highly volatile and diffuse rapidly in the substrate, however, in which cases compositions obtained from elemental analyses slightly differ from those of the precursors. Low-firing lead-free glazes maturing at 1050 °C or less (Seger Cone #2) have one to two parts of silica per part of the other ingredients.

Higher-firing glazes melting at ~1250 °C (Cone 10) have three to five parts of silica per part of others. High-temperature fired porcelain glazes have ~10 parts or more of silica (Table 1).

These empirical rules are now complemented by fundamental insights derived from advances made through studies of structure–composition–property relationships (cf. Section 2). Lowering of the melting temperatures by network-modifying cations such as Ca, Na, K, Li, or Pb is well understood, as are the opposite polymerizing effects induced by the addition of Al. Raman spectroscopy (Chapter 2.2) is in particular used for rapid and nondestructive analyses of chemical bonds. The degree of polymerization of the coating is, for instance, derived from the ratio between the peak areas of SiO₄ bending and stretching modes (Figure 5), which markedly increases from fully depolymerized lead-rich glasses melted at about 700 °C to 3-D connected silica-rich glazes melted at about 1400 °C (Figure 5b and c) [14, 15, 18–22]. This direct relationship clearly illustrates how craftsmen have been unknowingly playing with the composition and degree of polymerization of their coatings to achieve the required properties.

Finally, the duration of the complete heating and cooling cycle is of course another important parameter, which is largely determined by the thermal resistance efficiency

Table 2 Modern glaze compositions expressed with Seger formula.

of the insulating materials of the kilns. Many weeks were necessary for Chinese Dragon medieval kilns and a week was still common in the nineteenth century. Until the 1960s, complete firing cycles were then down to several days. Thanks to the replacement of bricks with oxide-fiber felts in the 1980s, they have now been reduced to a few hours or even a few minutes for floor tile production.

3.2 Metal Enamels

Bonding the glaze with the metal substrate involves a reaction with the oxidation layer formed at the metal surface. Copper and iron alloys have been first used because they develop easily on heating an adhesive oxide film. Coat and ground layers are added in modern enamels deposited on steel. Fluor addition promotes the reaction and the bonding (Table 3) [4].

3.3 Micro- and Nano-Structure

As determined by the starting materials and firing conditions, coatings display a wide variety of microstructures such as thin (Figure 6a) and thick (Figure 6b, e, and f) glaze layers or single (Figure 6a and c) and multi (Figure 6b, e, and f) glaze layers. When examined in section, Iznik fritware represents a good example of a complex multilayered glaze that results from many firing sequences. The thinner glassy coatings are obtained by the *salting* technique whereby NaCl, lead oxide, or plant ashes are poured (and volatilized) in the kiln, generally by the chimney when the kiln had reached its top temperature. The body can have a high (Figure 6a) or a low porosity (Figure 6b, e, and f), or no porosity at all (Figure 6c and d). Coarse quartz grains are obvious in Figure 6b, e, and f bodies (composite bodies exhibit a better mechanical strength). Examples of underglaze (Figure 6c) and overglaze (Figure 6d) painted décor are given. Note in Figure 6f, the very characteristic Iznik white quartz slip made of angular, crushed grains.

Because the glaze is almost liquid at the firing temperature, it is rather difficult to keep a sharp separation between adjacent colored areas. Different techniques have been used to limit this drawback, namely, direct

painting on the green or porous body (underglaze décor), conservation of a line free of glaze precursor (often drawn with an oil-rich solution to avoid wetting by the glaze aqueous precursor, the *cuerda secca* technique), or addition of a highly refractory material such as either chromite [FeCr₂O₄] or spinel [(Mg,Fe)(Al,Cr)₂O₄] in Timuride and Iznik productions (Figure 3e) or hematite in Mamluk glass-enameled artifacts (Figure 3c and d). Furthermore, the hematite matt layer can be used as a rough substrate to attach physically a thin gold foil [18]. Another notable property of nonstoichiometric crystals such as spinels and chromites is their ability to catch diffusing ions.

Actually, many glazes contain micro or nanocrystalline secondary phases so that they are actually glass-ceramics (Chapter 7.11). Indeed, if the particle size is lower than ~1 μm, the optical clearness is kept. This is the case of calcium-rich glaze in which wollastonite [CaSiO₃] precipitates, common for Chinese and Vietnamese stonewares and *Celadons* [5, 9, 13], as well as for eighteenth-century soft-paste European porcelains. The growth of the crystalline second phase yields a specific décor largely experienced at the end of the nineteenth century and in contemporary creation (Figure 7d) [6]. Metal nanoparticles are another type of nanoprecipitates used as coloring agents as will be described in the next section (cf. Chapter 6.2).

4 Coloration

The color palettes on porcelain of the very beginning of nineteenth century of the Sèvres Manufacture (Figure 7a) are nice illustrations of the hues that were then obtained [11, 19]. Here, variations in hues were also determined by the different thicknesses of the enamel and small modifications of the composition [10, 11, 23]. As a general rule, the higher the firing temperature, the more difficult is the conservation of a large palette of shades. Because coloring agents were used in rather small quantities, elemental analyses either are not very efficient to identify them or involve very localized (destructive) methods [14, 24, 25]. Along with diffuse reflectance spectroscopy, Raman spectroscopy has proven to be the most efficient technique [2, 13, 15, 18–24, 26] especially when the frequency of the exciting laser is slightly higher than that of an electronic transition (the scattering intensities of bands coupled to this transition are then enhanced, and interferences with other bands reduced, which makes it possible to probe selectively chromophoric sites).

Glazes and enamel are colored in the same way as bulk glasses (Chapter 6.2). The simplest coloring agents are ions exhibiting electronic transitions in the visible range,

such as transition metals (Fe^{2+} , Fe^{3+} , Co^{2+} , Cu^{2+} , Mn^{2+} , Mn^{3+} , V^{3+} , V^{4+} , etc.) or rare earths (Pr^{3+}), which are incorporated into the glass network. Depending on the ion, contents in the 0.1–1 wt % range generally suffice for efficient coloration. Because the electronic energy levels depend on the structural environment of the ion, the actual hue varies with the chemical composition of the glass matrix (Chapter 6.2). The effect is especially strong for Cu^{2+} , which yields turquoise and green colors in alkali- (Figure 2d) and lead-based (Figure 1d) silicate glasses, respectively. The variety of colors achievable in this way is limited, however. Other routes have thus been developed, especially for thin layers in which pigments can be incorporated without dissolving in the glass matrix if they are refractory enough [4, 6, 9–13, 19, 26–30] (Tables 4 and 5). Good examples are spinels, corundum [Al_2O_3], garnets [$\text{X}_3\text{Y}_2(\text{SiO}_4)_3$], and zircon [ZrSiO_4], whose very slow dissolution rates may actually cause real problems in glassmaking (Chapter 1.2).

A crystalline matrix can be specially prepared as a host for coloring ions to enhance color and tune it more precisely. The pigment then is synthesized independently and incorporated into the batch. The reactivity of the pigment should be sufficiently weak to avoid its dissolution/modification in the molten glaze, however, which is why highly refractory phases with compact structures such as spinels, corundum, garnets, and zircon are good matrices in this respect (Tables 4 and 5) [24].

Ancient pigments were usually silicate- and lead-based compounds. The same cuprorivaite structure [$\text{MCuSi}_4\text{O}_{10}$] has been used by Egyptian and Chinese craftsmen to prepare blue pigments, but with different alkaline earth cations, Ca and Ba, respectively. Natural pigments, such as lapis lazuli, a semiprecious lazurite feldspar colored through doping by S_x ions (Figure 3b and c), have been used at least since the Ptolemaic Dynasty to color pottery glaze and enamels on glass objects [18]. In the beginning of the seventeenth century, Johann Friedrich Böttger (1682–1719) took advantages of the high coloring power of lapis lazuli to whiten the glaze of the first porcelains made in Europe in Saxony at the Meissen Factory (Figure 2f) [31]. Alternatively, saturation in certain element leads to precipitation of phase(s) on cooling. Such a secondary phase precipitation can be tailored to opacify the glaze as done with cassiterite [SnO_2], fluorite [CaF_2], calcium antimonate [$\text{Ca}_2\text{Sb}_2\text{O}_7$], lead arsenate [$(\text{Pb,Ca})\text{AsO}_4$], and phosphates [2, 10, 11, 13, 24, 30–33]. Unmixing (Chapter 5.2) is another type of phase separation that is tailored for special effects, for example, for *aventurine*, *flamé* (Figure 7c), or *fur hare* (Figure 7d) glazes, sometimes in combination with the formation of copper or iron metal particles, respectively [34].

A third way is to use metal nanoparticles (formerly called colloids) as pigments or as light-diffracting agents.

Table 4 Pigments used in the twentieth to twenty-first centuries.

Pigments	Crystal structure	Color
$\text{Co}(\text{Al},\text{Sn})_2\text{O}_4$	Spinel	Blue
CoSiO_4	Olivine	Blue
$\text{CoAl}_x\text{Cr}_{2-x}\text{O}_4$	Spinel	Blue-green
$(\text{Zn,Fe})(\text{Fe,Cr})_2\text{O}_4$	Spinel	Black
CuCr_2O_4	Spinel	Black
$\text{Zn}(\text{Al,Cr})_2\text{O}_4$	Spinel	Pink
$3 \text{CaO} \cdot \text{Cr}_2\text{O}_3 \cdot 3 \text{SiO}_2$	Sphene	Victoria green
$\text{Pb}_2\text{Sb}_{2-x}(\text{Sn,Si,Fe...})_x\text{O}_7$	Pyrochlore	Naples yellow
$\text{ZrSiO}_4 : \text{V}$	Zircon	Blue
$\text{ZrSiO}_4 : \text{Pr}$	Zircon	Yellow
$\text{ZrSiO}_4 : \text{Fe}$	Zircon	Pink
$\text{ZrO}_2 : \text{V}$	Zircone baddeleyite	
$\text{SnO}_2 : \text{V}$	Cassiterite	Yellow
$\text{Al}_2\text{O}_3 : \text{Cr}$	Corundum	Ruby
$(\text{Al,Cr})_2\text{O}_3$	Corundum	Red
Cr_2O_3	Corundum	Green
$\text{Fe}_{2-x}(\text{Al,Ti,Mn})_x\text{O}_3$	Hematite (corundum)	Red
$\text{Fe}_{2-x}(\text{Al,Ti})_x\text{O}_3$	Hercynite (spinel)	Red
$(\text{Co,Ni})\text{O}$	Periclase	Gray
$(\text{Co,Zn})_2\text{SiO}_4$	Phenacite	Blue
$(\text{Ti,Ni,Nb,Cr,Sb})\text{O}_2$	Rutile-cassiterite	Brown
$(\text{Sn,V})\text{O}_2$	Rutile-cassiterite	Yellow
ZrSiO_4	Zircon	White
ZrO_2	Zircone	White
$\text{CdS}_{1-x}\text{Se}_x$	Wurtzite	Yellow (S) to red (Se)

Light is absorbed through its interaction with the electron gas formed at the metal/dielectric matrix interphase (Figures 1b, 2d, 7d and 8). The strong peak observed in the UV–visible absorption curve (Figure 8d) is due to the plasmon resonance of this electron gas and the broader features due to interband electronic transitions [27]. Typically, particles of gold, copper, silver, and iron yield ruby, red, yellow, and gray colors, respectively. Glaze colored with colloidal gold has been spuriously named Cassius purple [24, 27], after the chemist Andreas Cassius (1605–1673). The formation of metal nanoparticles requires controlling redox equilibria within the glass. Burning wet wood to produce hydrogen, which diffuses rapidly in the glass network, was a simple way to do it. Another, indirect way was fast diffusion of multivalent

Table 5 Main ancient pigments.

Pigments	Structure	Composition	Color	Date
Lazurite (Lapis lazuli)	Feldspathoid	$\text{Na}_8\text{Al}_6\text{Si}_6\text{O}_{24} : \text{S}_x$	Ultramarine	Roman
Ultramarine	Zeolithe	$\text{Na}_8\text{Al}_6\text{Si}_6\text{O}_{24} : \text{S}_x$	Ultramarine	> ~1830
Co-olivine	Olivine	Co_2SiO_4	Blue	>1500
Sèvres blue	Spinel	CoAl_2O_4	Blue	>18th

Copper	Metal nanoparticle	Cu	Red	<5th BCE
Silver	Metal nanoparticle	Ag	Yellow	12th

ions reduced at the glaze/enamel surface ($\text{Fe}^{3+/2+}$, $\text{Sn}^{4+/2+}$, $\text{Sb}^{5+/3+}$, and $\text{Eu}^{3+/+}$) [27, 28, 35]. Good examples demonstrating how aesthetic combinations of red and turquoise colors can be achieved through the different oxidation states of Cu ions obtained in kilns (Figure 7c) [32–36] are *Jun*, *flammé*, and Art Nouveau pottery.

A fourth method of coloration is based not on light absorption but on diffraction. The technique is extensively found in Nature (opals, mother of pearl, butterfly wings, beetles, cephalopods, or tridacna). The color arises from constructive/destructive interferences formed by the quasi-periodic organization at the layer nano-level. This surface effect is called *luster* (French *lustre*, from the Latin *lustrare*, to illuminate) (Figures 1b, 7d, and 8a). It dates back to the Islamic Abbasid dynasty (ninth

century) [27, 35–37] during which the alternation of layers rich and poor in metal particulates forming the luster was achieved by controlled sequences of oxidizing/reducing atmospheres by deposition of a mixture of Ag/Cu salt, clays, ocre, or organic compounds (vinegar, grape must, etc.) on the already glazed surface of the pottery. On heating ($\sim 600^\circ\text{C}$), silver and copper ions diffuse in the glaze and form metal nanoparticle-rich layers under the action of the reducing atmosphere and redox equilibria. Then the precursor mixture is eliminated by washing and the luster décor revealed [27, 35].

Gilding or *silvering* are yet other methods to coat a glass artifact with a colored metal layer of Au (Figures 1a, f, 2b, c, e, 3c [traces]) or of silver (Ag) [37]. Brass and mercury alloys are also used [39]. The metal layer can be bonded

Figure 8 Glaze colored with metal nanoparticles. (a) Dish made by Eva Haudum, potter (note the golden and red shine for a given orientation; photo E. Haudum, diameter ~ 15 cm); (b) TEM images of a Fatimid luster pottery (twelfth century, Egypt) and (c) of a *pigeon blood* red glaze (Source: Courtesy Ph. Sciau, CEMES-CNRS, Toulouse); (d) comparison of the visible-light absorbances of a glass with and without 0.25 wt % Cu metal nanoparticles.

chemically or physically, thanks to a rough surface. Different techniques initiated during the Renaissance are possible (addition of Bi_2O_3 , resins, etc.). Finally, one obtains a white color by dispersing a second phase with a particle size comparable to that of the wavelength of visible light and a refractive index differing from that of the glass matrix. Examples are air bubbles, quartz, cassiterite (Figures 1f, and 6b), fluorine (Figure 1d), calcium phosphate, lead arsenate, zircon, or zirconia.

5 Enamels

5.1 On Metals

Early craftsmen first solved the fluidity problem by the *champlevé* technique (from the French *champ*, the background of the shield, in heraldry, and *levé*, removed), whereby the metal substrate was carved to form rifts that

retained the molten glass in the intended decorative pattern during the firing. More intricate decors were achieved in the second century BCE through the replacement of the carved regions with thin walls made up of metal foils called *cloisons* (thin walls, in French), a thin metal strip perpendicular to the substrate delineating the different colored areas and forms depicted (Figure 1d). The first were made by Celts on various metals and in Byzantium, mainly on gold. The *champlevé* and *cloisonné* productions on gold or silver substrates flourished throughout the Byzantine Empire and in neighboring Kiev and Georgia Kingdoms, as well as in the Western Carolingian Kingdom and Otton's Roman Empire (seventh to eleventh centuries) [2, 33]. In the twelfth and thirteenth centuries, Limoges (France) and Silos (Spain) became large production centers in relation to the Muslim culture of *al-Andalus*. Silver substrates were then used in Italy from the fourteenth century. Examples of compositions are given in Table 6.

Table 6 Mean compositions of some enamels on metal substrates.

Type	Origin	Date century	SiO ₂	CaO	K ₂ O	Na ₂ O	PbO
Painted	Limoges, Burgundy, Venice	15th	39–70	2.5–5	3–16	7–16	0–22.4
		16th	42–55	5–6.5	1–5.5	8–8.5	23–35
		16th	55–73	3	5–8	5–10	—
		16th–17th	62	4.5	4.5	—	2.5
		17th–18th	61	3.1	5.5	—	13.8

Source: After [2].

A medieval Chinese report calls enameled work *production from the Devil countries* (*guiguo yao*), i.e. the West [33]. When the production of *cloisonné* enameled objects nonetheless eventually developed in China from the sixteenth century (Figure 1d), the technique had almost declined in Europe. The reason had been the emergence toward the end of the fifteenth century [2] at Limoges of a *painted enameling* (Figure 2a and b), an elaborate technique in use at the same time in Burgundy and the Netherlands as well as in other parts of France and Europe. Painted *Limoges* enamels consist of multilayer paintings deposited on a copper support through successive firings of different compositions (Figure 2a and b). The back side is also enameled and the *cloisonné* artifact polished after firing. This technique called *falang* (Frank, in Chinese) was more sophisticated than earlier ones such as *champlevé* with which the same glass matrix can be used for different colors. Like the potters of the *majolica* ceramics, craftsmen depicted very complex motives from episodes of antique legends or biblical themes. Around 1530–1540, yet another new kind of enamel employed a limited number of colors, mainly black and white (hence the name *grisaille*, grayness), to enhance the visual effects in the flesh areas of the human figures depicted. During the seventeenth century, the quality of enamels began to decrease until a remarkable revival took place in the nineteenth century: the workshops not only produced modern *Limoges School* pieces but also replicas of Renaissance enamels that were also often being sold as originals (Figure 2b) [2].

5.2 On Glass

Even though high-quality glass artifacts have been produced in large quantities ever since the beginning of Roman times (Chapters 10.3 and 10.4, [18, 23, 37]),

dichroic/luster and enameled glass (Figure 1a, and 2b, c) are very rarely reported in the ancient literature [10] or represented in museum collections [18, 23, 37]. Major examples of preserved enameled glass objects are remains of the Afghan Begram Treasure (first century CE; Musée Guimet, Paris), the fragments of the Lübsow cup found in Poland (second century CE), or the Cohn Beaker and Hans Cohn Collection, which is supposed to have been found in Egypt [18, 23]. The evidence becomes infrequent from these early periods until the Islamic and Venetian productions of the thirteenth century. The few remaining pieces representative of the whole Byzantine period are a group of gilded and occasionally enameled vessels from Corinth and Paphos together with a series of sparse objects, all dated between the tenth and the eleventh century, and the famous San Marco Bowl also dated to the tenth/eleventh century and probably brought back to Venice after the sack of Constantinople in 1204 by the Crusaders.

With the enameling and gilding technologies developed at the Norman/Swabian Court of Frederik II (recent excavation at Melfi Castle, Southern Italy, thirteenth century) and in Syria and Egypt [18] during the Ayyubid and Mamluk periods, pieces were then exported all over the ancient World from Europe to China. Mamluk Mosque lamps, mostly hanging, are among the most magnificent evidence of the technical virtuosity of those glassmakers. The use of lapis lazuli as ceramic or glass pigment has long been denied by scholars. But the presence of lapis lazuli powder, sometimes mixed with cobalt ore, has recently been demonstrated in pottery glazes and glass enamels of the fourteenth century [18]. Furthermore, a more ancient use of lapis lazuli has been documented down to the first century or even before with the glass treasure discovered in Afghanistan at Bēgrām or Ptolemaic glazed pottery from Pompeii [18].

The development of chemistry at the end of the nineteenth century offered a variety of routes to color a glass matrix and enamels. In France, Philippe-Joseph Brocard (1831–1896) and Emile Gallé (1846–1904) were very innovative craftsmen famous for their masterpieces (Figure 2c) [38]. Brocard's approach, the mixing of a variety of coloring agents, may have been related to his self-teaching of glassmaking, as opposed to the more traditional technology so that his expertise in various fine arts was representative of the nineteenth-century technical innovation spirit. On the other hand, Gallé took advantage of his traditional glassmaking expertise to create new forms, with innovative shapes and color associations, contributing to the novelty of Art Nouveau aesthetics. The most striking innovations at the turn of the nineteenth/twentieth century was the use of $\text{CdS}_{1-x-y}\text{Se}_x\text{Zn}_y$ semiconductor nanoprecipitates to prepare vivid red to yellow and of UO_2 ions for yellow glaze [4, 10, 26].

6 Glazes

As produced in the Middle East from about 2000 BCE, glazes were fired at about 900–1000 °C and colored or opacified with lead antimonate yellow [$\text{Pb}_2\text{Sb}_2\text{O}_7$] and calcium antimonate white [1, 24, 33]. More elaborate techniques were then designed, for instance, in Egypt by potters of the 22nd Egyptian Dynasty (945–715) who took advantage of an efflorescence phenomenon on the sample surface during the drying process to form an in situ layer of glass/coloring agent precursor [1]. Another notable feature was the real mass production achieved not only by Roman glassmakers (Chapter 10.3) but also potters with *sigillata* (stamped earth), for instance, exported in the first century as far as Syria, Egypt, and the Black sea from the Graufesenque workshops in Central France. The surface layer was intermediate between a glaze and a slip and colored with hematite [Fe_2O_3], hercynite spinel [FeAl_2O_4], or pseudo-brookite [$(\text{Fe}^{3+}, \text{Fe}^{2+})_2(\text{Ti}, \text{Fe}^{2+})\text{O}_5$] [25].

In the Far East, Chinese Eastern Han to Sui potters (second BCE to seventh century) really initiated high-temperature firing technology, thanks to the building of advanced kiln. Temperatures higher than 1300 °C were achieved as early as in the third century for the feldspathic Yue stoneware [5, 9]. The first glazes obtained using plant ashes were used as décor (Figure 1e) in a fashion that looks very modern from an aesthetic point of view.

White porcelains then appeared during the Sui and Tang Dynasties (seventh to eighth centuries) [5, 9]. At the same period, Islamic potters found how, when combined with low-temperature firing, the (fifth century) Roman glassmaking technique of opacification by cassiterite [SnO_2] could compete with high-temperature

fired porcelain to produce artifacts with complex depictions [5, 9, 34, 36]. This innovation resulted from the imitation of the three-color Tang Chinese porcelain wares with lead-rich blue and green glaze dots deposited on a faience/*terra cotta* body covered with an alkaline glaze [9]: the chemical reaction between the two glazes caused white cassiterite to precipitate. The use of cassiterite opacifier spread around the Mediterranean Sea with the expansion of the Islamic World, namely, in *Ifriqaya* (seventh century), *al Andalus* (eighth century), Sicily (ninth century), and then to Italy (*majolica*, thirteenth century) and France (fifteenth to sixteenth century) [29, 30, 35, 40, 41]. A composition shift took place from calcium-rich (ash-based) glazes during the tenth-century Five Dynasties to potassium-rich (feldspar-based) Song glazes (twelfth century) [5, 9]. Interestingly, a similar evolution took place with delay in Vietnam from the Ly to the Tran dynasties between the eleventh and fourteenth centuries [13]. Examples of compositions are given in Table 7.

Blue-and-white Yuan porcelains were first prepared with cobalt pigments that could come from Iran (or Saxony, Europe) through the Silk Road, thanks to the *Pax Mongolica*. Local cobalt ores were then used, but these Asian sources had high Mn and Fe contents. Especially when their fuel was coal, Chinese and Vietnamese potters empirically controlled the firing atmosphere of their kilns to obtain the strongly reducing conditions required to produce the blue color desired [9, 13]. As optimized in China, the blue décor was drawn on the body (underglaze décor, Figure 6c) or on the glaze (Figure 6d). The first technique was optimized in China while Vietnamese potters preferred overglaze décor.

Attempts to imitate the blue-and-white Chinese porcelain were first made by Islamic potters. Top-quality pieces were made in Anatolia, for instance, at Iznik (the ancient Nikaia) where manufacturer(s) developed fritwares between around 1450 and 1620 (Figures 6e, f, and 7b) [42]). In Italy, the Duke of Medici's porcelain (Figure 2e), a material intermediate between fritware and hard-paste China, was produced from about 1575 to 1587 with the help of a Master coming from the Levant [41]. At the end of the seventeenth century, manufacturers of soft-paste porcelain (silica-rich body made of a quartz grain cemented with a glass, a sort of fritware) appeared in France (Rouen, Saint-Cloud, Paris, Chantilly, Vincennes, Tournai, and Mennecey) before factories of hard-paste porcelain (Figure 2f) developed in the whole of Europe (Meissen, Strasbourg, Vienna, or Saint-Petersburg) [19, 40, 41]). Also called China, hard-paste porcelain is made from kaolin and feldspar. It is an alumina-rich body transformed into acicular mullite crystal frame (~30% in volume) soaked with a glassy matrix. The major difficulties were to build kilns reaching 1450 °C and to maintain such high temperatures for a few days. Consequently, the first European tentative at Dresden to fire

Table 7 Mean compositions of some glaze layers on terra cotta, stoneware, and hard- and soft-paste porcelain bodies.

Source: After [5, 9, 11, 13].

hard-paste porcelain relied on a solar beam and lenses! Iznik potters first used a cassiterite opacifier in a lead-based glaze but rapidly replaced this technique by a layer made of crushed quartz grains covered by a transparent glaze (Figures 6e, f, and 7b). These grains act as light reflectors that give rise to the powerful colors of Iznik décors. The very efficient control of Ottoman authorities, the *Nakashame*, led to an exceptional quality of production for about a century [42]. Later, Kütahya manufacturers (Figure 1c) maintained the creativity of Ottoman glazed fritwares. Ottoman potters produced multilayer glazed artifacts requiring multi firing cycles (Figure 6e and f). The soft-paste porcelain route can actually be considered as an evolution of the Iznik fritware

technology since the body consists of quartz grains cemented with the frit. When kaolin was eventually discovered in Europe in the eighteenth century, its availability allowed for the preparation of hard-paste alumina-rich porcelain. Its high refractoriness led to design new glaze compositions. A revolution thus took place after 1750 with the development of fine faience and porcelain factories in Europe [19, 24].

Elegant white Song porcelains were largely exported, including in Japan. Throughout the thirteenth to sixteenth centuries, however, some Japanese scholars began to prefer Chinese and Vietnamese stonewares. Their simplicity and imperfections were more highly praised than the highly aesthetic Song style (tenth to thirteenth

centuries), as a result of the *wabi-sabi* Movement and the development of the Tea Ceremony [43]. During the Momoyama period (1573–1615), local potters, in particular those of the Raku Family, already very active, developed a highly original style (Figure 1f). Unpredictable kiln effects (i.e. defects!) were desired for these “accidentally lovely” works used as flower vases and utensils for the Tea Ceremony [43]. The discovery of this production at the first *Expositions Universelles* (World fairs) led to the *Japonism* and *Craft* aesthetic movements, which have largely inspired a large part of the contemporary pottery production. These have even been at the roots of the renewal of the *cloisonné* enamel technique in Europe at the end of the nineteenth century.

7 Perspectives

The second half of the twentieth century has seen extensive merging of companies in the ceramics and glass industries. Enamels formerly made in traditional manufacturing processes are now produced by a limited number of companies, which has led to a standardization of technologies and products. Only rare creative potters made again their enamels themselves. The best control of the heating (kiln) and insulation processes have also strongly modified the procedures whereas wood firing has almost disappeared. Some coloring elements have become either too expensive or toxic, in which case they are now prohibited (e.g. UO_2^{2+} yellow, CdS – CdSe red to yellow). As another example, the European Union plans to prohibit the use of lead, even if its encapsulation in silicate networks guarantees the absence of a reaction. Searches are being conducted to replace lead with other fluxes such as boron and bismuth although it remains to establish whether the new compounds obtained are actually less prone to release undesirable elements. On the other hand, sol–gel routes (Chapter 8.2) allow coatings to be processed at much lower temperature [44] than the usual ceramic and glass routes, which has led to innovative products such as enameled aluminum kitchen stoves.

Venetian Glass

Marco Verità

Stazione Sperimentale del Vetro, Venice, Italy

1 Introduction

That Venice has been the world leader in glassmaking from the middle of the fifteenth to the end of the seventeenth century is illustrated by Venetian artifacts exhibited in museums and collections all over the world. Venetian glassmakers always fostered innovation in terms of novel compositions, new glass designs, and applications so that their production was exported throughout Europe and the Levant. Even today the high-quality glass produced on the island of Murano is still living up to this long-standing tradition.

Several secrets were at the basis of this success:

- The style of Venetian luxury glassware and the skill of glass masters.
- The high quality of glass and the rich palette of colors, resulting from continuous improvements in the selection of raw materials and in the melting process.
- The variety of glass products such as luxury blown glass, but also tableware, lamps (*cesendelli*), chandeliers (since eighteenth century), window panes, mirrors, beads, glass for mosaics, enamels for metals and glass, imitation of gemstones, buttons, pigments for painting (smalt and *giallolino*), lenses for eyeglasses (Galileo Galilei selected Muranese mirror glass to make the lenses of his first telescope in 1609), glassware for alchemists, glass spheres for military use (to be filled with explosives), or even from the sixteenth century enameled glass for mosque lamps.

Throughout the centuries the development and success of the Venetian glass industry were strongly related to the support it was receiving from the

Venetian Republic which, in turn, exerted a tight control on it. As first documented in a 1271 text, glassmakers were, for instance, not allowed to leave the Republic and work in other countries to prevent trade secrets from diffusing out of Venice. Whereas the production of luxury glass was reserved to native Muranese glassmakers, luxury items could be sold only by the workshops where they were produced. As a matter of fact, these workshops had to alternate periods of production and of extinction of the furnaces in order to avoid overproduction. From the second half of the fifteenth century, product promotion was even provided since important personalities visiting Venice were brought to visit glass workshops in Murano (*Veder far veri a Muran*). Likewise, the Venetian government strictly protected the trade of the raw materials that were essential to obtain high-quality glass, ensuring regular supplies and forbidding their export to other glassmaking centers, but was forbidding the use in Murano furnaces of low-quality raw materials such as the potash plant ash in use in northern Europe.

The sources available today for a historical reconstruction of the Venetian glassmaking technology include archeological finds, analyses of glass remains, and historical documents. A significant number of archeological glass finds from the Venetian lagoon and towns near Venice (Ferrara, Padua, Verona, etc.) dating to the seventh to eighteenth centuries have been uncovered up to date. Archeological evidence of glassworking has also been found not only in the town of Venice but also in the island of Torcello, the most ancient settlement established along the Venetian lagoon after the end of the Roman Empire that quickly became a distant outpost of Byzantium with which close cultural and trade relations were maintained.

Chemical analyses are available today for several hundred transparent Venetian glass samples, either clear or slightly colored [1–3]. These analyses concern glasses from museum collections and archeological finds, including waste glass and crucible fragments. Although the dating of most of the analyzed samples is generally reliable, it may be less so, for instance, when specimens found in an island of the lagoon were related to a building that had been in use for a long time.

Regarding historical documents, the fundamental reference for the study of Venetian glass is the chronology drawn up by Luigi Zecchin [4]. As stated by H. Tait [5], his researches “among the archives have done so much to correct long-established misconceptions and provide a sounder basis for the interpretation of the tangible remains from one thousand years of glassmaking in Venice.” Important contributions by other authors have also become available more recently.

Manuscripts drawn by the Venetian glassmakers themselves represent a unique source of information in this respect. These books date from the fifteenth century until today; they collected trade secrets written in the form of recipes describing how to select and process the raw materials, to prepare the batch, to color the glass, etc. As indicated below, some of them have been published.

- Three booklets (*Trattatelli*) attributed to the Tuscan glassmaking environment are kept in the State Archives of Florence, highlighting in some recipes the influence of Venetian technology. Their dating is still uncertain, ascribed to between late fourteenth and early fifteenth centuries by the first publisher [6] but to fifteenth (first half n. 1 and 2, second half n. 3) by L. Zecchin who extensively studied and commented them.
- The so-called Montpellier treatise, dated 1536 and also commented on by L. Zecchin [4].
- The *Anonimo* of the sixteenth century (reporting also recipes of the fifteenth century), the recipe book of a unknown Venetian glassmaker published in Italian and then translated into English [7].
- The treatise begun by Giovanni Darduin in 1644 who reported the secrets of his father Nicola (d. 1599) and then collected other recipes from different sources. After his death (1654), another author transcribed a number of recipes in an MS dated 1693–1712 [8].
- The recipe book of the Venetian glassmaker Brunoro found in Gdansk (Poland) written in 1645, including several North-European recipes demonstrating that the Venetian glassmakers working abroad experimented also with other techniques [9].

As for the famous *Arte Vetraria*, the first printed book devoted to glassmaking published in 1612 by the Florentine priest Antonio Neri (1576–1614), it also included a number of recipes of Venetian origin [10].

2 Raw Materials and Glassmaking

The oldest extant document related to the origins of Venetian glassworking is a manuscript dating from 982 CE, where a certain *Domenicus fiolarius* (Domenic the glassblower) is mentioned. Several documents of the eleventh to twelfth centuries then also mention the work of glassblowers.

The earliest documents reporting technical information are dated 1233 and 1255. They attest the import of raw glass and glass cullet from the Levant, suggesting that initially Venice was a center where glass made elsewhere was remelted and worked. The full glassmaking cycle is attested since 1255 (import of plant ash from the Levant) and 1275 (import of sand to make glass).

For fire safety, the glass industry was confined from November 1291 to the island of Murano where glass furnaces are still currently active. Only small furnaces for the production of imitation of gemstones were allowed to remain in Venice. From its origins to the end of the Venetian Republic (1797), the base material for the main production of Venetian glass objects was a soda-lime-silica glass. Historical sources describe the use of two basic raw materials.

Silica was used in the form of imported sand from the Levant, Crete, and Sicily or, from 1332, of better-quality pebbles from Ticino and Adige rivers (northern Italy) reduced to a finely ground silica powder suitable for melting. The use of pebbles instead of sand testifies to the efforts made in Venice to have a silica source less contaminated by coloring elements such as iron than the silica sands available.

As a flux, the Venetians used a soda ash obtained from burned coastal halophyte plants such as *Salsola soda* or *Salicornia* growing on high-salinity grounds. Already mentioned in ancient documents as *alume catino*, soda ash was imported from the Levant and Egypt (the latter of lower quality). From the sixteenth century, the import of soda ash from Spain (*barilla*) and southern France is also mentioned. Despite being considered of lower quality, this ash was increasingly used in the following centuries probably because of a diminution of the trade with the Levant. Unsuccessful attempts were also made during the eighteenth century to grow in the Venetian lagoon the plants to produce the flux.

In spite of its high freight charges, soda-plant ash was imported because it was a reliable raw material whose composition remained constant over a period of several centuries and allowed high-quality glass to be produced with the empirical technical knowledge available at that time. These ashes were complex mixtures of sodium and calcium carbonates along with of chlorides, sulphates, minor amounts of potassium, magnesium, iron, aluminum, silica and other elements, and coloring

contaminants at low levels. Lime is an essential stabilizing ingredient, the lack of which led to alkali leaching from the glass surface and weathering phenomena. This effect was first fully understood probably in Bohemia in the seventeenth century. During the Middle Ages and Renaissance, lime was thus unintentionally introduced in the right proportion with soda as a secondary component of plant ash.

A small amount of potassium (as 2–4 wt % K_2O) was also introduced through the soda ash (and feldspars present in the silica source). In some Venetian recipes, potash was deliberately added to the batch in the form of *grepolà* (tartar), the deposit of wine barrels, added in a calcined form (K-carbonate), or unprocessed (black tartar) as a reducing agent to obtain particular colors. Studying the Venetian recipes of the fifteenth to seventeenth centuries, P. Zecchin observed that the amount of tartar added to the glass batch increased progressively in this period [11]. Saltpeter (potassium nitrate) is rarely mentioned in recipes before the end of the seventeenth century.

The preparation of a lead silicate glass to be added to the batch, giving a soda-lime-lead-silica glass, is attested in Venetian treatises exclusively for the production of colored glass for the manufacture of rods, beads, imitation gemstones, enamels, and mosaic tesserae. The use of lead to improve the optical quality of colorless glass is found in Venetian treatises only from the end of the seventeenth century.

As first mentioned in a 1290 document, manganese dioxide was the decolorizer used by Venetian glassmakers to neutralize the color caused by the iron contaminants of the raw materials (Chapter 6.2). It was imported from Piedmont (Italy), Catalonia, Germany, and France. The Venetian glassmakers took great care in the decoloration process and brought it to perfection. Manganese was first added in small amounts to the batch. More of it was then added directly to the melt until decoloration was perceived. The addition of manganese was thus minimized, which manifestly improved the optical quality of glass. Arsenic and antimony associated to saltpeter were also used as decolorizers in Venice from the end of the seventeenth century.

Even though it was not mentioned in written documents, a very early trade of glass to Venice is attested by findings in the Adriatic sea, a few km off Venice, of a ship wreck with several hundred kilograms of raw, clear natron-type glass approximately dated eighth century [3]. In Venice, utmost care was taken in the selection of the cullet to be used for melting high-quality glass. Only in common clear glass elements indicating recycling have been detected analytically in trace amounts, namely lead and tin pointing to recycling of *lattimo* (a partially crystallized milky-like glass, Section 4.2.2) and copper to that of colored glass. Similar trace elements are found only rarely in high-quality *vitrum blanchum*, and *cristallo* (see Section 4.1).

Batch melting is attested in Venice from the thirteenth century, but was probably already practiced earlier. The process was performed in two steps, each workshop preparing its own batch. The first took place in a reverberatory furnace, the *calcar*, where the mixture of soda-plant ash and silica in nearly equal weights was calcined for several hours or days at about 800 °C to obtain the frit, an intermediate crystalline product. The batch had to be continuously stirred to avoid the formation of a vitreous liquid phase. The reactions taking place during this treatment led to the elimination of the carbonaceous compounds of the ash (avoiding undesired colors), the decomposition of carbonates (leading to release of gases and to better glass fining), and the transformation of the high-melting silica into alkali and alkaline earth silicates.

In the second step, the frit was melted in a crucible in a wood-fired furnace at about 1200 °C, possibly mixed with glass cullet and coloring and opacifying compounds. Analyses of crucible fragments of the eighth to thirteenth centuries found in Venice and Torcello have revealed the use of soapstone (magnesium silicate) whereas documents of the fourteenth to fifteenth centuries indicate that the crucibles were then made with clay imported also from Constantinople. During melting, one had to remove with a long-handled iron spoon the insoluble chlorides and sulphates present in the plant ash making up the scum floating on the surface of the glass, which otherwise would have affected glass transparency. A Venetian document dated 1348 mentions the technique of casting molten glass into water and remelting it subsequently. When repeated several times, this procedure helped to increase glass homogeneity by removing residual chlorides and sulphates salts, which were dispersed in the melt as small droplets and made the glass “obscure and cloudy.”

3 The Origins of Venetian Glass

3.1 The Transition from Natron to Soda-Plant Ash Glass

A number of scenarios have been debated for the origins of Venetian glassmaking. Besides more plausible hypotheses, some are clearly fantastic, to say the least, such as its introduction by Byzantine mosaicists of the eleventh to twelfth centuries, glassmakers from Altare embarked from Venice in 1096 for the First Crusade, or certain Benedictine monks.

The assumption of a direct connection with the Roman glassmaking tradition is based on the fact that Aquileia, a Roman town not far from Venice, was a famous glass-working center until the fifth century CE. Upon arrival of the Barbarians, Aquileia was destroyed and its inhabitants moved to the Venetian islands where they resumed

their activities, including glassmaking. Remains of glassworks were uncovered in 1960 during an archeological excavation close to Torcello’s cathedral. The initial hypothesis that they were related to the production of the mosaic tesserae for the basilica has been proved wrong by later analyses [12]. Instead, they attest to the presence of a glassworking activity on the island that has been dated to the seventh to eighth centuries, and was limited to the remelting of glass cullet and the blowing of items of naturally colored natron-type transparent glass (Chapter 10.3).

A second hypothesis associates the flourishing of Venetian glassmaking to the strong trading and political ties existing between Byzantium and the *Serenissima Repubblica*. In the tenth and eleventh centuries, Venetian

Figure 1 Changing origins of Venetian glass evidenced by variations in the analyzed MgO and K₂O contents from the fifth to the fourteenth centuries (time intervals indicated by Roman numerals).

merchants obtained the trading privileges from the Byzantine emperors that gave them a distinct advantage over their competitors from other western European cities. In that way, Venetians acquired Byzantine art and adapted and imitated its techniques, including the art of glassmaking that had not undergone the decadence brought about it in Europe by the fall of the Roman Empire.

As a matter of fact, valuable light on the origins of Venetian glass has been thrown by chemical analyses of clear samples dating from between the fifth and the fourteenth centuries. With respect to K₂O and MgO, the samples fall in two groups, which correlate with the relative ages of the glasses (Figure 1, Table 1). The earliest are characterized by the lowest fractions of K₂O and MgO, along with P₂O₅ contents lower than 0.2%, which point to the so-called natron glasses made by melting a silica-lime sand with natron as a flux. In some more recent samples of the eighth to twelfth centuries, non-negligible contents of tin, antimony, lead, and copper have been found. The presence of these coloring/opacifying elements at concentrations too small to affect transparency and color is considered as an indicator of remelting of glass cullet, which also contained polychrome opaque glass. The second group shows higher and more dispersed K₂O, MgO, and P₂O₅ contents. It represents glasses obtained by melting a batch of silica and soda-plant ash at a later period.

A few samples with intermediate concentrations of magnesium, potassium, and phosphorous (see Figure 1) probably indicate melting of mixtures of natron and plant-ash glasses. That in this period the two kinds of glass could be mixed to be remelted together is confirmed by the twelfth-century shipwreck found at Serç Limani (southern Turkish coast) whose cargo included three tons of raw glass and Islamic glass cullet of both natron and soda-ash types.

This transition from natron to soda-ash glass in the Venetian area is clearly pictured by the time histograms of Figure 2, where a marked change in the proportions of natron, natron-recycled, and soda-ash type glasses gradually took place between the eighth and thirteenth centuries. Until the seventh century, only natron glass

Figure 2 Transition from natron to soda-ash glass demonstrated by a histogram representing the fraction of analyzed samples belonging to each compositional group in the four time intervals considered: N, natron; NR, natron recycled; ASH, soda-plant ash; INT, intermediate composition between natron and plant ash type.

was used (1/5th recycled). Between the eighth and the eleventh centuries, the first plant-ash glass appeared at a time where almost 1/3rd of the natron glass was recycled. During the tenth to twelfth centuries, plant-ash glass represented almost half of the production, whereas natron glass was becoming mainly recycled. A few samples having an intermediate composition also date from this period. Finally, in the thirteenth to fourteenth centuries, almost all of the analyzed samples are of the plant-ash type.

A similar transition occurred in the Levantine world in the same period [13]. The presence of wood-ash glass has not been found, which further confirms a Levantine influence on the origins of Venetian glass. A group of objects and common glass scraps dating from the eleventh to fourteenth centuries could represent the earliest evidence for batch melting in Venice [14]. They are naturally colored transparent glasses with a level of contaminants (Al_2O_3 , TiO_2 , Fe_2O_3) higher than found in other samples of this period. The latter were probably produced by remelting of high-quality glass cullet imported from the Levant.

3.2 Torcello Mosaics

The technique of colored metal (silver or gold) leaves firmly adhering to hot glass slabs, which subsequently

protected them from oxidation and enhanced their brilliance, was first designed by the Romans (first centuries CE) and subsequently developed in Byzantium and Islam to make mosaic *tesserae*. Those of the eleventh to twelfth century Torcello mosaics give an interesting insight into the origins of Venetian glassmaking as they widely predate the earliest documents attesting in 1308 the manufacture of mosaic glass slabs in Venice, which permitted the production of 1500 *lingue* (i.e. tongues, gold- and silver-leaf elongated glass slabs) for the mosaics of St. Mark's cathedral in Venice, and in 1359 of other *lingue* for the Orvieto cathedral. An origin for the Torcello mosaics excluding a Venetian production has thus been suggested [15]. The raw glass would have been produced in Islam, then exported to Byzantium where it would have been remelted and colored. The *tesserae* (or glass slabs) would then have been manufactured and brought to Torcello by Byzantine mosaicists.

Against this explanation, which is not supported by factual evidence, one should note that chemical analyses distinguish between two groups of *tesserae*: whereas one was made with natron glass and opacified with calcium antimonate, the other (and more abundant) group was made instead with soda-plant ash glass and opacified with ground quartz. Now, the latter technique was peculiar to Byzantine *tesserae* as illustrated by other mosaics of this period made at Daphni and Hosios Loukas in Greece or at Monreale in Sicily. However, the glass of these *tesserae* is similar but not identical to that of Torcello, suggesting the use of similar but not identical raw materials to melt the glass [16]. Since glass *tesserae* subsequently made in Venice in the fourteenth century for St. Mark's mosaics are similar to those of Torcello, it seems justified to conclude that the Byzantine production technology of mosaic *tesserae* was transferred to the Venetian glassmakers at the time the Torcello mosaics was made, and then consolidated in Venice in the following centuries.

4 Venetian Renaissance Glass

4.1 The Secrets of Cristallo

Until the middle of the fifteenth century, Venetian glassmakers produced two qualities of clear glass (earliest documents, 1290), the so-called *vero comun* (common glass) and *vitrum blanchum* (white glass). We can suppose that *vero comun* had a slight green to yellow or blue natural hue, and that *vitrum blanchum* distinguished itself by the lack of any hue it had as a well-decolorized gray glass. As stated in Section 2, the glass quality was improved, thanks to four factors, namely the use of the less contaminated quartzite pebbles instead of natural sand as a silica source, direct addition of manganese into

the glass melt, careful selection of glass cullet, and casting of the molten glass into water.

Around the middle of the fifteenth century, a more dramatic change took place when a new glass called *cristallo* (crystal) was invented by the Muranese glassmaker Angelo Barovier (d. c. 1480). This name indicates a transparent glass with so much better optical properties (supposedly: perfect decoloration, less gray hues, and high light transmittance) than the traditional *vitrum blanchum* that it could be compared with natural rock crystal. *Cristallini* has been the term used since then to indicate items made with *cristallo* glass. Not only blown objects but also rods and beads were made with the new glass used also as a base material for transparent and opaque colored glasses.

The secret formula of *cristallo* was one of the main factors that allowed Venice to maintain its predominance over other European glassmaking sites for about two centuries. Venetian recipes dwell on the ways of obtaining *cristallo*. All of them agree that its “secret” lies in a preliminary step to be included into the usual procedure, which consisted in the purification of the soda-plant ash: the raw ash was dissolved in boiling water and the resulting solution was then decanted, filtered, concentrated, and dried to obtain a white salt called *sal de cristallo*. In general, one part of purified ash and one of powdered silica were mixed and calcined to prepare the *cristallo* frit, which was then melted for two days in a crucible. The glass was then poured in water several times and finally either decolorated by addition of manganese or colored with the appropriate elements.

The *cristallini* obtained in this way would have been practically sodium silicate glass because the purification process eliminated also the insoluble calcium and magnesium carbonates together with undesired iron compounds. It was thus unsuitable for making any kind of glass pieces since the lack of chemical stabilizers would have caused *cristallini* to bloom and crizzle even shortly after production. Of course, the well-preserved Venetian *cristallini* exhibited in museums and private collections demonstrate that Muranese glassmakers did search for a solution to this problem and found it.

The making of alkali silicate glasses almost free of lime and magnesia was nothing new. The existence of this kind of glass is attested by Florentine *basse taille* enamels of the fourteenth century, thus made well before the invention of the *cristallo*. A procedure similar to the aforementioned purification of plant ash was actually followed for preparing them. But stability against weathering was actually ensured by coloring agents such as copper and iron oxides, whose contents could reach 10 wt % to obtain the intense color sought after for the enamels to be thinly deposited on metals [17].

Analyses of fifteenth to seventeenth century Venetian clear glasses have allowed the secrets of the new *cristallo* glass to be deciphered. The analyses initially made [18] have now been confirmed by further work performed on more than 150 glass samples that were first classified visually. Samples with slight natural hues were termed “common glass” whereas colorless specimens were designated as either *vitrum blanchum* or *cristallo* depending on their more or less gray appearance, respectively. Iron and aluminum are contaminating elements of the raw materials considered as good indicators of their sources. Although there is some overlap between their contents in the three glass categories (Figure 3), distinct trends can nonetheless be identified as also shown by the compositional data gathered in Table 2.

The alumina and iron contents are the highest in common glass samples, indicating that these were made with the most contaminated silica sources. The 0.5–1 wt % alumina content of the *cristallo* samples is comparable to the values found for part of the *vitrum blanchum* samples (0.6–1.7 wt %). In contrast, the 0.2–0.4 wt % Fe_2O_3 content of the former is lower than the 0.3–0.8 wt % values found for most of the latter samples. Finally, it appears that the CaO (2.5–6.3 wt %) and MgO (0.5–2.4 wt %) contents in *cristallo* samples are significant; they are about half those of *vitrum blanchum* and common glass and show the same Ca/Mg ratio of about 3:1 as in the two other groups. The easiest way to obtain the *cristallo* composition was thus to melt a frit mixture of *cristallo* (free of alkaline earths) and *vitrum blanchum* in roughly equal amounts. This process yielded a glass of higher optical quality than *vitrum blanchum*, and ensured sufficiently high amounts of calcium and magnesium to stabilize the glass against weathering.

4.2 Other Renaissance Venetian Glasses

4.2.1 Enameled Glasses

The production of enameled glass is attested in Venice from 1280 until 1351 and then continuously since the middle of the fifteenth century. In the first period, the so-called Aldrevandin beakers were produced, whose name comes from the inscription below the rim of one specimen exhibited at the British Museum. In the nineteenth century, these beakers were attributed a Levantine source, in part because of a similar enameling technique used in Mamluk Islam to decorate precious vessels. The rediscovery of a number of records of painters of beakers operating in Venice between 1280 and 1351 and chemical analyses [19] have definitively ascribed them instead a Venetian origin. Although generally minor, the differences in composition between Aldrevandin and Islamic beakers are clearcut for the blue enamels that were

obtained with lapis lazuli powders by Islamic glassmakers and a cobalt blue glass by the Venetians.

Renaissance gilded and enameled glasses, mostly showpieces decorated with coats of arms, mythological scenes, etc., were made in Venice from the middle fifteenth through the seventeenth centuries (Figure 4) with a technique known from the description given in the second half of the fifteenth century by a manuscript kept at the University Library of San Salvatore in Bologna (MS 2861). Individual colors were obtained with glasses having different chemical compositions with different softening temperatures. After enamel powders had been deposited on it, the object was returned to the glassblower

for the firing process which was making the decoration permanent. The item was reheated, reattached to the pontil, exposed to the fire of the furnace until the enamels were fused, and then annealed. This process required great skill to prevent the object from being distorted and to avoid compromising the quality of the design by the difficulties raised by the differing viscosities of the molten enamels.

4.2.2 Lattimo

Lattimo (milk-like) was the Venetian term to designate the opaque white glass used until the middle of the fifteenth century only for the preparation of mosaics

Figure 4 Renaissance Venetian gilded-enameled ewer, c. 1530, height 20.9 cm, max diam. 12.7 cm (Museo del Vetro, Murano, Classe VI, n. 1004).

tesserae, enamels, and for small applications on blown glass. It was then improved by Angelo Barovier at Murano for producing luxury blown glassware to be gilded and enameled. This new glass was initially called *porcellano* (porcelain glass), because it was used to imitate oriental porcelain items that had just appeared in Venice. Objects

of *latesin* (light blue-gray opaque glass colored with copper or copper and cobalt) used for rare and precious objects are also mentioned in some documents dated 1496 and 1508.

Recipes to prepare *lattimo* report first the preparation of a lead-tin calx (lead and tin calcined together generally in a ratio of 1:1). Comparable amounts of *cristallo* frit and lead-tin calx and smaller amounts of silica were then mixed, calcined (frit), and melted. Manganese was added as a decolorizer. Analyses confirm that *lattimo* glass of fifteenth to sixteenth centuries was opacified by tin oxide crystals (cassiterite) dispersed in a soda-lime-lead-silica glass.

The term *lattimo* as applied to blown glassware appears for the last time in the Muranese documents in 1714. It continued to be used only for decorative threads and enamels. For blown objects, the new *smalto* (first in 1693) was then used. It was prepared by addition of arsenic oxide, saltpeter, and lead oxide to the traditional batch of *cristallo*. The *smalto* was opacified by micrometric crystals of lead arsenate, homogeneously dispersed, giving an intensely opacified glass with better properties (viscosity of the melt, smoothness of the surface of objects) and was less expensive than traditional tin-lead calx *lattimo*.

Other opacifiers such as calcium antimonate (from the mid-sixteenth century) and, less frequently, calcium phosphate (bone ash) are also mentioned in recipes. Darduin reports two recipes to make opaque white glass with antimony, which he describes as a rediscovered secret (*segreto ritrovato novamente*). It is not clear how the use of antimony reappeared in the glassmaking technology after a thousand years since it was a tradition in the Roman world. The chemical composition of Venetian white opaque glasses is reported in Table 3.

Filigrana (filigree) was invented in Murano in 1527 and further improved around 1540. This sophisticated decorative technique makes use of thin opaque glass threads twisted in different ways, encased in clear glass and incorporated into blown objects (Figure 5). The difficulties of working together *lattimo* and clear glass arose from the

Table 3 Chemical composition of opaque white Venetian glasses (wt %).

different viscosities of the two glasses and the tendency of *lattimo* to form lump. They were overcome by Muranese glassmakers by a skillful technique involving rods made of a thin layer of *lattimo* between two layers of *cristallo* (Figure 6). The outer layer could be a colored glass, for instance, to prepare blue and white filigree.

4.2.3 Colored Glass

“There is no kind of precious stone which cannot be imitated by the industry of the glass workers,” wrote the historian Marco Antonio Sabellico (c. 1436–1506) when dealing with Venice [20]. Colored glass was indeed one of the most distinctive aspects of the glassmaking in Venice where the manufacturing of colored glass rods, beads, and millefiori items is attested from 1338. Toward the end of the Republic in the late eighteenth century, these items even met with so much success that they became the major glass products made in Venice.

Colored glasses imitating natural gemstones (*verixeli*) are attested in Venice from 1281. The recipes deal with imitation of a variety of stones, e.g. blue (sapphire, lapislazuli, aquamarine, turquoise), yellow (amber, topaz), green (emerald, chrysophase), ruby red (ruby, cornelian, coral, garnet balas), purple (amethyste), and clear (rock crystal). Soda-lime-silica as well as soda-lime-lead-silica glass (with or without addition of potash) were used for this production that was exported to Europe and the Levant.

Angelo Barovier is to be recognized also as the inventor of chalcedony (Table 4), a layered glass with brown, red, purple, and yellow translucent or opaque layers (Figure 7) [21]. Venetian recipes for chalcedony call for a

(a)

(b)

Figure 6 The thin *lattimo* glass rod embedded into a *cristallo* glass as seen in an oblique thin section examined by optical microscopy (a) and with scanning electron microscopy, back-scattered electrons (b).

lead-soda-lime-silica glass composition with coloring elements such as iron, cobalt, and copper; an amount of silver of about 1000 ppm was added directly to the molten glass immediately before shaping as nanoparticles coloring agent (Chapter 6.2). The chemical composition of a fragment of a sixteenth century Venetian chalcedony is reported in Table 4. Once the object had been fashioned,

Table 4 Chemical composition of colored Renaissance Venetian glasses (wt %).

Figure 8 Metallic copper particles dispersed in a nineteenth-century aventurine glass seen under the optical microscope.

the glassmaker was instructed to return to the furnace hole several more times to heat it until the chalcedony colors were seen.

Not to be confused with the homonymous green variety of quartz, *aventurine* (Table 4) is characterized by foliated, sparkling metallic copper particles dispersed in the clear (or blue colored) glass (Figures 7 and 8). It was mentioned for the first time at the beginning of the seventeenth century, but probably invented at the end of the sixteenth. Darduin [22] explained that the name *venturina* came from the fact that such a glass was extremely difficult to make and was obtained more by chance than by the skill of the glassmaker (*più per ventura che per scintilla*). Because copper was introduced as an oxide, the difficulty was first to reduce it with elements such as iron, lead, or tin (or even with cereal semolina) added to the melt at high temperatures and then to let the formed metallic Cu nucleate and grow crystals upon slow cooling down to the glass transition [22]. The chance character of the process thus resulted from that neither the overall chemical composition of the starting materials nor the thermal treatments were precisely controlled.

Given the importance played by temperature in both redox reactions (Chapter 5.6) and crystal nucleation and growth (Chapter 5.4), the temperatures obtained and their rates of change were often inappropriate to optimize reduction of copper oxide and especially formation of the Cu large crystals needed to ensure the quality of the final product.

The name *girasole* (sunflower) refers to a translucent, opalescent, dichroic glass changing its color from light blue (reflected light) to yellow reddish (transmitted light). The first reference to *girasole* glass appears in Neri's book, 1612 (Book 4, chapter 74), whereas the first mention in the Ricettario Darduin dates from 1 June 1693. The chemical analysis of a sample of the eighteenth century is reported in Table 4. The recipes for *girasole* and *smalto* are similar, prescribing addition to the *cristallo* batch of lower amounts of potassium nitrate, lead oxide, and arsenic oxide, which induced the separation of lead arsenate microcrystals [23].

Yellow pigments to color glass were called *anime* (souls) in Venice, with reference to the facility with which their color faded away during the shaping of the object.

The procedures to prepare *anime* in a range of colors from lemon yellow to orange brown are reported in Venetian recipes, which refer to lead stannate, lead antimonate, and lead-tin antimonate compounds [24]. The *anime* were added to a transparent, colorless (or green) molten glass and roughly stirred. The instability of the pigments once added to the soda-lime glass is emphasized by the recommendations to mix rapidly the *anime* with molten glass outside the crucible, on a metal plate.

5 *Façon de Venise* Glass and Competition

The rapid spread of Venetian glass was duly noticed by the clergyman William Harrison (1534–1593) [25] who wrote in his *Description of Elizabethan England*:

it is a world to see in these our days, wherein gold and silver most aboundeth, how that our gentility, as loathing those metals (because of the plenty) do now generally choose rather the Venice glasses, both for our wine and beer, than any of those metals or stone wherein before time we have been accustomed to drink.

From the sixteenth century onward, the increasing demand for Venetian fashionable luxury items encouraged a number of Muranese glassmakers (soon followed by Altarese glassmakers [see Section 6.2]) to set up glassworks all over Europe, where objects imitating Renaissance Venetian glass were produced in spite of the official bans. *Façon de Venise* productions are, for instance, recorded in Vienna (1486), Ljubljana (1526), Hall in Tyrol (1534), Antwerp (1537), Bohemia (1557), in the second half of the sixteenth century in London and later in Amsterdam (1597).

In most cases it is difficult to distinguish with the naked eye between genuine Venetian and *façon de Venise* glasses in view of their same styles and decoration techniques. Chemical analyses can be much more sensitive [26]. Three main compositions of *façon de Venise* glass have been identified: potash-lime-silica, mixed alkali lime-silica, and soda-lime-silica glass. The first two are typical of Northern Europe but were never made in Murano. The distinction between *façon de Venise* and genuine Venetian products is more complex for soda-lime-silica glass. Minor and trace elements characteristic of the silica source can help to distinguish them, however, Venetian glasses having, for instance, rather lower Zr concentrations in the 20–40 ppm range than *façon de Venise*.

Scientific investigations have been conducted within the framework of a project aimed at characterizing Renaissance Venetian enameled glass production and at providing analytical evidence to help distinguishing objectively these

items from contemporary *façon de Venise* or later imitations. In this case, analyses of enamels allowed further distinguishing criteria to be obtained [27]. For instance, particular chemical compositions are found, such as mixed-alkali base glass in *façon de Venise* blue enamels indicating the use of smalt (a potash-silica glass containing up to 8% of CoO used as a pigment). According to the written sources, Venetian glassmakers used an impure oxide named *zaffer*, and not smalt, as a cobalt source whereas the base glass of the blue enamels is of the soda-lime-silica type.

Besides the emigration of Venetian glassmakers, other reasons caused the decline of Venetian luxury glass toward the end of the seventeenth century. Neri's book (1612) unveiling secret Venetian recipes was translated in the following decades into English, Latin, German, French, and Spanish and probably inspired some of the experiments carried out by the inventors of new glasses in other European countries. In addition, glasses more brilliant and clear and less expensive than the Venetian *cristallo* were invented. This was the case of the potash-lime-silica crystal glass perfected by Johannes Kunckel (~1630–1703) in 1676 in Bohemia and of the lead (flint) crystal glass patented in England in 1674 by George Ravenscroft (1632–1683).

From the end of the seventeenth century onward, however, Muranese glassmakers attempted to renew their traditional *cristallo*. For instance, Giuseppe Briati invented a potash crystal glass similar to the Bohemian crystal glass. On the other hand, Venetian recipes of this period report the addition of significant amounts of lead to *cristallo* glass along with new decoloration processes with arsenic (or antimony) and saltpeter. But these attempts were not successful so that the Muranese luxury glass production decreased and nearly disappeared after the fall of the Venetian Republic. Venetian glassmakers did react to competition by specializing on other products. The manufacturing of small mirrors (in contrast to large mirrors made in France) to be exported in the Levant and glass beads destined in extremely high amounts for European colonies increased. Indeed, by the second half of the eighteenth century, the Venetian glass production had doubled in size compared to two centuries earlier [28].

6 Other Italian Glassmaking Traditions

Little is known of other glassmaking sites that were active in Italy (Milan, Ferrara, Mantua, Naples, and many others) during the Middle Ages and the Renaissance. It appears, however, that most of the glassworkers came from Tuscany, Altare, or Murano whereas written evidence attests to the production of utilitarian objects and more rarely of luxury glass.

6.1 Tuscan Glass

The importance of glass manufacturing in Tuscany between the thirteenth and eighteenth centuries is well documented [29]. As embodied by Benvenuto Cellini, a field of excellence of the Tuscan glassmaking was the manufacturing of enamels, which greatly influenced goldsmiths in Flanders and in France. The Florentine *Trattatelli* reported a number of recipes concerning enamels production. The base glass was made from silica (usually pebbles) and soda-plant ash. Addition of calcined tartar and potash plant ash was also reported. The fluxes were used as received or after purification. The technologies to make enamels in a wide range of colors and to opacify them are also described.

Archeological evidence of blown glass production in Tuscany dates back to the thirteenth century in the Valdelsa region. From the end of the fourteenth century and during the Renaissance, the glass workshops were generally established near large towns. Several documents describe the presence of Tuscan glassmakers in Murano during the fifteenth to sixteenth centuries, so that a production of luxury glass in Tuscany can be assumed.

Analyses of glass remains from workshops active during the fifteenth to sixteenth centuries indicate the making of soda-lime-silica glass. Some differences allow compositional groups to be identified [30]. A group characterized by low-alumina (Al_2O_3 1.5–2.5 wt %) and low-potash (K_2O 1.8–3.3 wt %) contents could have been made from silica pebbles and soda-plant ash imported from the Levant. A second group with high-alumina (Al_2O_3 3.5–5 wt %) and high-potash (K_2O 2.5–9.0 wt %) contents could have been made with a Tuscan silica sand rich in feldspars and the ashes of soda plants like barilla imported from Spain or southern France, but the voluntary addition of a potash source cannot be excluded.

6.2 Altare Glass

Altare in ancient Monferrato (today's Liguria), not far from Savona, has been a most important glassmaking center from the Middle Ages to the nineteenth century. The earliest document mentioning local glassmakers dates back to 1179. During the fifteenth century, more than 20 masters owned a glass furnace in this town. Whereas the guild kept a close control on glassmakers in Venice, regulations in Altare were much more liberal: the glassmakers could freely establish glassworks elsewhere so that they contributed much to the spread of glassmaking knowledge all over Europe [31].

Some Altarese glassmakers are related to significant innovations in the history of glass. Bernardo Perrotto (~1640–1709), for instance, obtained a French royal privilege to produce gold-ruby glass by using arsenic and gold

in his workshop in Orléans. This happened in 1668, that is 16 years before Johannes Kunckel began production of gold-ruby glass with another process relying on tin and gold on a rather large scale.

The Altarese Giovanni Odaccio Formica (fl. late seventeenth century) was working for Ravenscroft when he patented crystal glass in 1674 in England; he left Ravenscroft soon after and moved to Dublin (Ireland) to make lead crystal glass under another Royal patent. At that time, Ravenscroft opened a glasshouse at Hanley, where the master glassmaker was another Altarese, Giovanni Da Costa.

Whereas the activity of such Altarese glassmakers working in Europe is well documented, very little is known of their glassmaking technology for neither archeological evidence nor analytical data for genuine Altare glass items are available at present.

7 Perspectives

A sufficiently comprehensive picture of Venetian glassmaking from its origins to the Renaissance is emerging as a result of documentary research, archeological research, and chemical analyses. Some aspects concerning the provenance, dating, and selection of the samples limit the information obtained. Further analyses of well-dated samples of certain provenance are required for this purpose.

The compositional distinction between the Venetian and Levantine and *façon de Venise* glass production will require analyses with high-sensitivity techniques and determinations of the isotopic compositions of the samples.

Although the seventeenth and eighteenth centuries are generally considered as a period of decline for Venetian glassmaking, they were characterized by a great renewal in competition with other glassmaking centers in Europe. The considerable amount of written evidence available for this period has not been thoroughly examined so far, and relevant analytical data are almost completely lacking. The same can be said for the nineteenth century – the century of the Muranese glass rebirth – and for the twentieth century.

Only few analyses of colored Venetian glass have been published until now, and a comprehensive picture of this peculiar Muranese production is far from being accomplished.

Enormous amount of glass were made at certain periods to make beads, which became the predominant production in the eighteenth century. The required palette of colors was extremely broad in spite of the requirement that the thermal expansion and viscosity of the different glasses used to make polychrome beads had to be

matched. As very few analyses exist, specific research on available documents and materials deserves further study. Equally insufficient are the analyses made on imitation gemstones.

Little is known so far of other Italian glassmaking centers. The major innovative role played by Tuscan glassmakers in the medieval production of enamels is still underestimated because of the scant information available. Altarists introduced major innovations in glassmaking and contributed to develop the glass industry north of the Alps. Unfortunately, the Altarists' glassmaking tradition is still nearly unknown.

Stained Glass Windows

John M. Parker¹ and David Martlew²

¹ Department of Materials Science and Engineering, The University of Sheffield, Sheffield, UK

² Ecclestone, St Helens, UK

1 Introduction

Throughout the time of the Roman and Byzantium Empires, and later in much of Europe, glass competed with less expensive materials such as waxed linen, shell, horn, sheets of mica, or thin layers of alabaster as a means of glazing. In the brilliant sunshine of the Mediterranean region, limiting the light transmission and reducing solar heat gain in summer were significant factors in window design. As the Romans extended their domain northward, however, the importance of achieving adequate internal light levels increased and the greater transparency of glass was at a premium. Over the same period, the introduction of colored glass sheets offered new decorative possibilities. Consequently, for those who could afford it, glass became the material of choice. The resultant demand stimulated its production, motivated process improvements (Chapter 10.9), and simultaneously inspired architectural developments [1].

Glass windows were used by the Romans in domestic settings and civic buildings, but the availability of sufficiently large sheets led the expanding Christian community to use them in churches not solely for lighting and decoration but also for spiritual reasons. Genesis, the first book in the Bible, spoke of God's first creative act as a division of light and darkness. Phrases like "Then God said, *Let there be light; and there was light*" underpinned ecclesiastical thinking. Light and windows were inextricably linked. The stream of light into the main body of a relatively dark church would have shouted out to visitors, adding dramatically to a sense of worship; this feature

was widely appreciated in these early buildings even from Roman times as shown by comments in the literature of the period.

As early as the fourth century, the colored glazing of the basilicas in Constantinople was considered worthy of mention by the Roman poet Prudentius (348–aft. 415) in his praise of the good emperor who "covered the curves of the arches with splendid glass of different hues, like meadows that are bright with flowers in the spring" [2]. An advantage of colored glass recognized early on was the facility to display images in sizes much larger than those of individual glass panes. In addition to their spiritual and decorative effects, images of biblical and other religious themes represented valuable teaching tools at times when most people were illiterate and when, in the West, the Latin language of the liturgy was generally not understood. Colored glass was expensive, however, so that its use remained more common in religious than in civil architecture; only the wealthiest could afford it for their manors and princely houses. Until the nineteenth century, the development of stained glass has, therefore, been intimately connected with the evolution of its religious setting.

The limitations of cost as well as of technology restricted early glazing to simpler designs with a limited color palette and this still remains the case in the less critical areas of churches. Nevertheless, at least from the Byzantine period colored glasses have been organized into simple pictures representing aspects of the church's story. The fact that the only glass available was imperfectly flat meant that it would slightly distort the images of objects outside the building, making the window itself the center of attention and diffusing light sufficiently to avoid obvious transmitted images on the floors and walls. The introduction of silver staining in the 1300s added to the complexity of images that could be produced. It was

Reviewers: Ph. Colomban, Laboratory "From Molecule to Nano-object," Sorbonne Universités, Paris Cedex 05, France
J. Cooke and R. Cooke, Jonathan & Ruth Cooke Ltd., Ilkley, West Yorkshire, UK

another revolutionary step in developing decorative glazing, which was acknowledged by the English language in the nineteenth century when such glazing was termed *stained* rather than *decorated* glass.

Because the development of stained glass first and foremost relied on the availability of flat glass with fire-polished surfaces, this chapter begins with the crown and cylinder processes, the latter being still used. Attention will then be paid to the social contexts that were at the roots of the extensive use of stained glass in the West. Next, the ways in which glass was colored in the bulk, decorated on its surface, and integrated into a frame of lead strips are reviewed. Finally, the evolution of stained glass from the nineteenth century and the problems raised by the conservation of old, corroded windows are described. Given its limited size, this chapter is of course not comprehensive so that we refer to some of the many excellent papers and books available for more detailed accounts [e.g. 3–6]. Further information is also available from national and international organizations publishing research in the field. An example of such publications is the *Corpus Vitrearum Medii Aevi*, created at the initiative of the Swiss art historian Hans R. Hahnloser (1899–1974) in the form of an extensive series of illustrated catalogs of stained glass windows published by national committees under the auspices of the *Union Académique Internationale*.

2 Making Glass Sheets

2.1 Cast Window Glass

The oldest documented mansions and public buildings glazed with glass were built in the Roman Empire where transparent material was already produced on a large scale in the Levant in melting tanks whose capacity could reach 20 tons (Chapter 10.3). Initially, panes were made from glass cast in the molten state into a rectangular arrangement of iron bars forming a tray on a stone base perhaps covered by clay. Alternatively, the base might have been made of wet wood. Such large cast sheets have, for instance, been found in the glazing of Pompeii. A second-century bath-house window made by this technique in a Romano-British iron-working settlement at Hartfield, East Sussex, in the United Kingdom measured 235 by 255 mm and is now in the British Museum.

Inevitably, such glass slabs had a seriously disfigured surface where the glass contacted the solid casting substrate. In addition, rapid chilling of the molten glass followed by cooling of the thick slab gave rise to ripples on its lower surface while any sand, grit, or asperity on the casting substrate resulted in pock marks (Figure 1). It therefore fell into disuse until the end of the Middle

Figure 1 Cast Roman window glass: ~4–5 mm-thick, originally 35 × 80 cm panes, generally greenish, thinner at the edges with a fire finish on one side and a rough surface and tool marks on the other, found in a mid-third-century CE shipwreck off Ajaccio (Corsica) [7]. Source: Photo Hervé Alfonsi, ARASM; épave *Porticcio A*.

Ages when slow process improvements led to higher quality surfaces. These included the use of copper- and then iron-lined tables, the ability to suspend and control bigger crucibles over them so that larger sheets could be poured, the rolling of the hot glass, and the introduction of mechanical grinding and polishing in the early twentieth century (Chapter 10.9).

2.2 Crown and Cylinder Processes

In early Roman times, the introduction of blowing irons for shaping glass had also given a major stimulus to glass production, particularly of containers (Chapters 10.3 and 10.5). Because the new process allowed pristine glass surfaces to be produced with a fire finish, the idea came that, to have the same finish, flat glass had to be made from blown hollow ware. Two different processes were invented for this purpose. One was the *crown* method (Figure 2a). It involved first blowing a flattened bubble in the shape of a hollow disc, then attaching a *pontil* rod on the reverse side for support while opening the disc up where the blowing iron had been attached. Finally, the hollow disc was reheated and spun rapidly so that the centrifugal forces caused it to flip dramatically into a circular sheet of glass. The panes, which were significantly thinner than when produced by casting, were cut from the outer rim whereas the center where the pontil rod had been attached was of poorer quality and of less interest to the glazier. Of course, the imaginative window designer was sometimes able to incorporate such pieces with their *bull's eye* into his work.

The earliest samples of whole discs date back to the fourth century. They were small, measuring no more than 200 mm across. Because of the way it was made, this type of glass was slightly convex and had circular features, for instance, in the trails of bubbles trapped in the glass.

(a)

(b)

Figure 2 Final steps of the making of flat from hollow glass before annealing in dedicated furnaces as depicted in the *Encyclopédie* of Diderot and D'Alembert [8]. (a) Crown process: flattening by rapid spinning under the heat of the furnace of a vessel that was first blown, attached to a pontil at its other end, and opened wide on the blowing side; (b) cylinder process: cutting of the ends of a blown cylinder [a, b], longitudinal splitting with scissors [c], opening of cylinder [d], and flattening [h].

These make its origins identifiable even from relatively small fragments. Sections cut from a larger disc have been found in excavations near the church of San Vitale in Ravenna, Italy, dedicated in 547 CE, one fragment having evidence of rudimentary Christian symbols drawn on it [4]. The process continued to be developed over time. During the twelfth century, it became known as the Normandy method after its main area of production. Much larger discs could be made, thanks to further technical

improvements and to the greater quantities of glass that could be melted in a single pot. By the fourteenth century, these were up to 600 mm across. In 1700, the best discs were Dutch and reached 800 mm; Norman glassmakers responded to this challenge since their sales ledgers from 1724 reported that diameters of just over a meter (in modern units) were available [4].

The other method for making flat glass was that of the *cylinder* (Figure 2b). It also had its roots in Roman

Figure 3 The palette of hues described by Theophilus exemplified at the same period by the portrait of Hosea, one of the four prophets pictured in the 1130s in Augsburg cathedral. Glass probably made in the Benedictine abbey of Tegernsee, 100 km South-East of Augsburg. Modern framing of the stained glass with alabaster, a translucent material that could also be used for windows. Source: Photo P. Richet.

technology since it appeared toward the turn of the third and fourth centuries (Chapter 10.5). As part of a detailed picture of house glazing, its earliest description extant is that of the twelfth century by the German monk and priest Theophilus [9] according to whom a large palette of hues was commonly available, including *album* (white), *purpureum* (purple), *membranaceum* (flesh colored), *saphireum* (blue), *rubicundum* (red), *viridium* (green), *croceum* (gold yellow), or *luteal* (saffron yellow) (Figure 3). By swinging a blown bulb vertically, the worker stretched it in the form of an elongated cylinder and controlled its diameter by *marvering* it (i.e. rolling a glass gather on a marble table) and by manipulating it with

various tools. This *long bladder*, as termed by Theophilus, was finally cut longitudinally – hot with scissors or cold with a red-hot iron – opened and flattened with a type of wooden rake in a softening *lehr* to make a flat sheet. The product was variously known as *cylinder*, *broad*, *sheet*, *spread*, or *muff* glass. Sheets made in this way can be identified by the elongation of internal bubbles along the axis of the cylinder.

From the fourteenth century, Lorraine became a significant European center in the production of cylinder glass, thanks to abundant wood and high-quality sand resources and to immigrant labor from Bohemia where no doubt the early Roman traditions had been maintained and developed. Often termed *Lorraine glass*, this material was linked to a major improvement in quality, for example, less variability in thickness, and cylinders were up to 1.5 m long. By this time, improved controls of temperature and other operating parameters meant that both surfaces of cylinder glass were glossy, unlike those of early Roman production.

These manufacturing methods were steadily improved over the next centuries but not radically changed until the introduction of mechanized processes at the beginning of the 1900s (Chapters 1.4 and 10.9). At least early on, the crown method gave a higher quality surface finish – “brighter and more transparent” – because it was fire polished on both sides. It was more expensive, however, and involved a higher proportion of waste in its production and cutting as it could not yield panes larger than 16 × 12 in. out of crowns 30–32 in. in diameter [10]. Cylinder glass had the major share of production and differing requirements led to differentiation between Franco-German, Bohemian, and German, and Belgian, English, and American types [10]. In part, this diversification resulted from the desire to make “whiter” and bigger glass panes for larger windows. This required a change of composition toward those of *short* glasses (Chapter 10.5), which could be blown into cylinders that were not as long but had a larger diameter [11].

The final choice of crown, cylinder, or cast glass depended partly on application and partly on fashion, which could vary between different countries. Cylinder glass gave larger sheets but crown glass was of better optical quality. Costs were another factor, including taxation, and whether products of suitable quality were available locally or had to be imported. In the United Kingdom, crown glass remained available at least until 1832. Nowadays, sheets for replacement in ancient buildings and for making modern stained glass are still made by the cylinder technique because it remains the only method economically viable for small quantities (by industrial standards) of colored or special clear products. The Verrerie de Saint-Just in France, Lamberts in Germany, Spectrum in the United States, and many other companies are well-known suppliers of these glasses.

2.3 Glass Compositions

The geographical distribution of manufacturing sites evolved over the centuries. Early glassmakers had sufficient local wood supplies as their energy source and they used raw materials derived from around the Mediterranean basin, in particular, alkalis derived from the ash of seaboard plants or especially from the Wadi Natrun salt lake near Alexandria where sodium carbonate hydrate [$\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2 \text{H}_2\text{O}$, the *trona* mineral usually named *natron* by abuse of language] was extensively mined (Chapter 10.3). From the beginning of our era, the Levant, and particularly the Alexandria area, was the major glassmaking center from which not only exquisite products but also glass ingots were exported around the Mediterranean coast and ultimately into Roman-dominated regions as far as Iberia, Gaul, Brittany, the Low Countries, and Germany. Over time, the technologies of creating products by remelting ingots and recycled cullet spread too and by the first-century CE glassmaking had reached the city of Rome (Chapters 10.3 and 10.5).

While glassmaking suffered from the decline of the western part of Roman Empire, it remained prosperous in the East in Byzantium [12], especially in the form of mosaics, as well as in the lands that became part of the Islamic World. Particularly important from this standpoint was the shortage of natron that took place in the seventh to ninth centuries [13]. Local plant ash thus had to be taken as a substitute, but its composition was not only more complex but also more variable with, in particular, high K_2O contents in wood ash that made glass more prone to weathering. To the west, increasing fuel pressures in addition meant that glassmaking skills slowly

extended inland along major river systems such as the Po, Rhine, Vistula, and Danube with their wooded valleys [3, 4]. But these changes in glass production also led to important changes in the batch. Wood ash, particularly from beech trees, became the principal source of flux. A significant fraction of the glasses made were consequently more potassium rich.

The changes in the location of glassmaking over the centuries, the use of different raw materials according to availability, the international nature of trade, the recycling of older glasses, and ongoing improvements in technology have all contributed to a considerable variability in glass window compositions (Table 1). Superimposed on these real variations are measurement inaccuracies, which have been extensively investigated in recent years by round robin surveys, for example, by the Technical Committee 17 of the International Commission on Glass (Chapter 10.5), one outcome of which has been the creation of international reference samples. Many analytical techniques (Chapters 2.2 and 2.3) have been applied to determine both major and minor element concentrations in archaeological samples with the goal of increased understanding of provenance and glass production methodologies. These include (Chapter 2.2): X-ray fluorescence (nondestructive, handheld equipment is available, see Chapter 10.1); electron spectroscopy for chemical analysis (ESCA); secondary ion mass spectrometry (SIMS); ion beam spectrochemical analysis (IBSCA); neutron activation analysis (NAA), and Auger emission spectroscopy (AES).

Overall composition, the presence of minor elements, and isotopic ratios are all used to develop an understanding of historical trends and can provide information on the provenance of windows from individual ancient buildings and the raw materials used in making them

To be compared with the Mediterranean tradition of high soda and low potash exemplified by the compositions of thirteenth century panes in a rose window from Siena cathedral, namely, 56–64 wt % SiO₂, 13–14% Na₂O, 9–10% CaO, 2.5–4% K₂O, and 4% MgO.

[e.g. 14, 15]. In an electron-microprobe study of window-glass fragments [16], including many stained glass pieces from twelfth to eighteenth century Belgian archeological sites (Table 2), the 500 specimens were statistically grouped into five categories: high-lime, low-alkali (HLLA) glasses, three groups of high-potash glasses, and just a few high-soda glasses corresponding to specialist applications (e.g. mirrors). Stained glasses were more often in the high-potash group but not limited to it. Significant trends were: (i) an increasing silica content over time linked to changes in the sand to ash ratio used in glass melting from 1 : 2 to as low as 1 : 1; (ii) an increase in the K₂O : CaO ratio in the fifteenth to seventeenth century, suggesting a change in the fluxing agent and possibly the deliberate use of limestone; (iii) total alkali remaining constant even though the K₂O : Na₂O varied; (iv) the use of NaCl as a flux in later HLLA glasses; (v) higher MgO levels in the fifteenth to seventeenth-century compositions.

For comparison, the chemical composition of some medieval colored stained glasses from the (Cathedral) in Siena, Italy, are given in Table 2 [17]. They have much more soda and less potash and lime than the Belgian compositions, related to the different choice of alkali source as a flux for glassmaking in the Mediterranean area.

3 Social Context

Glassmaking continued during post-Roman (Byzantine) times for the next 500 years on a reduced scale. Few buildings constructed during this period have survived with

their glazing intact but, based on glass fragments recovered from excavations, colored glass panes were being used decoratively during the first millennium. Some were simply assemblies of regularly shaped pieces held in place by leading; this allowed larger windows to be glazed using small pieces. Actually, much architectural attention was paid during the first millennium to maximize the benefits of the light streaming through these windows in large buildings [1].

Images could also be created. An example in the United Kingdom was the church built at St Peter's Monkwearmouth (founded in 674 CE) by Benedict Biscop (~628–690) who went to Gaul to bring “some masons to build him a church in the Roman style,” as reported by his monk Bede the Venerable (~672–735), and then sent “messengers to Gaul to fetch makers of glass (more properly artificers) [...] that they might glaze the windows of his church” [18]. These windows have been interpreted as embodying the image of a simple figure created entirely by joining small colored sheets; none showed any indication of painting. More important, however, is that after the collapse of the Roman Empire, the Church helped to preserve these ancient skills and reintroduced them where they had been lost.

At the beginning of the second millennium, the economic, demographic, and political expansion in Europe led to an expansion in religious buildings of all sizes as witnessed by the numerous abbey churches and cathedrals from the eleventh century still extant. This growth stimulated the development of decorative glazing from its primitive beginnings. The wave of major construction projects was a seed bed for developing new skills. At this juncture an influential figure was the powerful Suger

(1081–1151), abbot of Saint-Denis, north of Paris, and adviser to the French king. Although large windows had already been made, for instance, in Bavaria at Augsburg (Figure 3), Suger gave them a special importance when he rebuilt his abbey church around 1135. In the ninth century, the patron saint of the abbey (a second-century martyr) had been wrongly identified with a sixth-century Greek mystical theologian who was himself assumed to be a first-century disciple of the apostle saint Paul and had taught that light was the vehicle by which the divine was perceived. Suger thus took advantage of extensive reglazing to teach about Old Testament “Types” of Christ and link them to New Testament incidents. Interestingly, he gave a prime panel spot at eye level, which thus served as an advertising space, to the craft guilds that financed a window, no doubt helping to defray the huge costs incurred.

The glass of abbey and cathedral windows was produced by independent manufacturers and sold via a middle man to the artists who turned it into the works of beauty we see today. It was never cheap. This meant that the later art of decorating the panes by painting not only became itself a highly valued skill but also resulted in extensive reuse of the materials themselves. One notable example is the famous window *Notre Dame de la Belle verrière* in Chartres cathedral, which had survived the devastating 1194 fire of the previous Roman edifice (Figure 4). Likewise, twelfth-century panels from a demolished section of York Minster were reused in the fourteenth-century nave in spite of the improvements in design between these periods.

A major change was then taking place because the use of buttresses in gothic edifices for supporting high walls made much larger openings possible, which could thus be extensively glazed in harmony with the bulk of the building [1]. The new feature was most dramatically illustrated by the 640 m² of stained glass installed in the 15.5 m high windows of the Sainte Chapelle, built in Paris from 1243 to 1248 to host relics of Jesus’ Passion such as True Cross and Crown of Thorns. This change gave the possibility of telling an extended story rather than simply teaching through a single image. Now the church wished its congregations to be instructed in its faith. Church Laws also encouraged adding images of Christ and the Saints, particularly those to whom the building was dedicated (Figure 5). This included statues, altar cloths, and screens but was particularly evident in window decorations.

The Black Death brought a temporary halt to the expansion of cathedrals throughout Europe, in the fourteenth century. Once it was over, however, major workshops rapidly developed again, often near major religious centers such as York in the United Kingdom, and an international trade flourished both in finished

Lower panels to be read from bottom to top and left to right, depicting the Three Temptations of Jesus by the devil (pictured as a beast) and The Wedding at Cana. The light blue of the original panel and the subsequent darker hue reflect a change in the cobalt source used. *Source:* Photo P. Richet.

windows and also in skilled workmen. But a major event in the early sixteenth century was the Protestant Reformation, which challenged throughout Europe tenets of the then current theology. A consequence was the extensive destruction of windows (along with statues, retables, or paintings), which were thought to foster idolatry; fortunately, many were saved simply because their replacement would have been too costly. The new windows made in the seventeenth and eighteenth centuries were thus made to bring as much light as possible to help reading of the Holy Books and watching the priest who celebrated the Mass. New stained glass windows were thus rare, with fresh designs that could be commissioned by either side of the debate to make their point (Figure 6).

As Europe became a safer place, beyond the ecclesiastical community, the gentry too were able to construct larger mansion houses with an increased proportion of

Figure 5 Jesus' crowning with thorns: the most important stained glass panel of the Sainte-Chapelle, in Paris, built to host relics of this crown. In all, 1113 scenes of Scripture depicted in the chapel, only five hues were displayed, namely, blue (cobalt), red and green (copper), yellow (antimony), and purple (manganese). *Source:* Photo P. Richet.

windows. It became the fashion to decorate them too, for example, with the coat of arms of the occupants. Large public buildings also followed similar practices.

4 Glass Decoration

4.1 Body Coloration

Whereas the aim of many early glassmakers was to achieve the ultimate in transparency, those working for architectural applications knew how glass could be colored by the addition of various kinds of *earths*, i.e. what are now termed metal oxides (Chapter 6.2, [19]). From the Roman period onward, body-colored sheets had already been made whereas the Greeks were coloring glass tiles in their walls to create mosaics. Old recipes had thus long been available to color glass, including those of glazers and enamellers whose range of colorants were similar (Chapter 10.8).

Early windows were small and had to provide adequate light levels. Nevertheless, by the twelfth century, church windows already included strong reds and blues. As the proportion of glazing increased, more light entered the building, giving glassmakers the opportunity to experiment with the concentrations of their “pot-metals” to create stronger colors. Interestingly, in medieval United

Figure 6 Noah's ark: a well-known Biblical scene pictured in Saint Étienne-du-Mont church in Paris at the beginning of the seventeenth century, at a time when little new stained glass was made. *Source:* Photo P. Richet.

Kingdom, colored glass sheets were sold by weight rather than by area and at twice the price of clear glass because the latter was of English origin and the former imported.

The oldest surviving windows are notable for the dominance of blue among the colored panels. An early colorant was cobalt ore (Chapter 6.2), which gave rich blues although the source of suitable material was limited. Depending on place and period, the blue glass created by the Egyptians relied on cobalt from local sources or imported from Iran and other areas. A similar substance called *zaffre* (Arabic for cobalt oxide) was extensively used in cathedral glass. An early source of this colorant, also known as Damascus pigment, was the Levant. Later, Saxony became a major supplier, in agreement with the fact that the term *smalt* designating cobalt-rich glass probably derives from the proto-German *smaltian* (to smelt). These ores could not be used directly for melting because they contained mixed cobalt sulfides and arsenide. They required pre-treatment to remove the sulfur and arsenic by volatilization and leave cobalt oxide [3].

Another source of cobalt was the residue from bismuth extraction.

Copper was widely refined by the metallurgical industries of the Roman period, which meant that copper-rich ore was readily available to glassmakers after appropriate processing. From its color, one can guess that such a source called *ferretto* was primarily cuprous oxide. Oxidized brass fillings were also used. As had long been familiar to Egyptian and Mesopotamian glassmakers, copper can color glass turquoise blue or green in its oxidized form [Cu^{2+}] depending on the composition of the base glass (Chapter 6.2). Iron oxide too can impart a pale blue hue to the glass if melted with a reducing flame so that the iron is predominantly in a reduced state [Fe^{2+}]. Mixtures of Co, Cu, and Mn are also common in blue glass, no doubt partly because of difficulties of separation in ancient times but primarily to produce a wider range of blue tints (Figures 3–5).

Iron oxides were difficult to avoid completely in the raw materials. They could usefully add a tint to the glass ranging from blue [Fe^{2+}] through green to yellow [Fe^{3+}]. Indeed, one could produce amber colors by melting glass under reducing conditions when sulfur was also present.

Empirically, Romans (Chapter 10.3) already knew the glassmaker's soap. We now understand that it was dissolved manganese, which acts as a decolorizer at low concentrations, reducing the green coloration normally present as a result of iron impurities by oxidizing ferrous iron [Fe^{2+}] to ferric iron [Fe^{3+}]. At higher 1–3 wt % concentrations, though, it colors glass purple [Mn^{3+}]. But solarization is an issue when high manganese concentrations are used as a decolorizer because the UV radiation in sunlight can reverse the oxidation of iron caused by the added manganese. Clear Mn^{2+} then becomes the purple chromophore Mn^{3+} . Glass that has been covered by leading and protected from sunlight can be a good indicator of the original color of a glass sheet and may be observed while a window is being repaired. Glassmakers might even have realized that additives such as arsenic and antimony salts added primarily for removing bubbles (refining) could influence the colors obtained, a phenomenon now understood in terms of a change of the balance of redox ions (Chapter 5.6).

Whereas blue was dominant in earlier church windows, over time the proportion of red increased (Figures 3–5). Ancient glassmakers had already discovered that a copper-containing glass melted under what is now termed reducing conditions can acquire a deep and intense red coloration (Chapter 6.2). The colorant in this case was precipitated cuprite (Cu_2O) or copper metal nanoparticles, which are both so strongly absorbing that, as discussed in the following paragraph, usually a thicker clear layer was combined with a strongly colored thinner layer to allow sufficient light transmission.

4.2 Casing/Flashing

Glass colored red by copper nanoparticles is so deep in color as to be opaque (Chapter 6.2). In a context of great symbolic significance since the red color was the symbol of Christ's martyrdom, two ways were successively followed to obtain the thin red glass required for light transmission. Both were unknowingly relying on two redox reactions [20]. In the first reaction, the virtually colorless cuprous ion is oxidized into the pale blue or green cupric ion:

In the second, the cuprous ion is in contrast reduced to copper metal by electron exchange with other ions such as the Fe^{2+} present in trace amounts:

In a process used from the twelfth to the fourteenth century, which did not have any precedent in the glass-making tradition [20], alternate layers of high- and low-Cu glasses, not always parallel to the surface of the glass sheet, were formed and produced close to their boundaries, within the latter layers, Cu^0 -rich, μm -thick red striations (Figure 7a). The process likely required first

Figure 7 The two processes for producing a red color with copper nanoparticles in Amiens cathedral (northern France). (a) Cross section of thirteenth-century striated fragment. (b) Cross section of a nineteenth-century transparent glass overlaid with a thin, strongly colored red layer, duplicating the simpler process used from the fourteenth century. Source: Photos Philippe Colombar.

the interlayering (without mixing) of a pale blue or green, oxidized Cu-rich glass and a colorless, reduced Cu-poor glass, which were heat treated to let Cu^+ diffuse into the latter to be reduced according to Eq. (2) and to nucleate the Cu nanoparticles; a gather of white glass was then dipped into the interlayered melt and blown to yield a cylinder of white glass coated by the mixed Cu glass in which the layer interspacing was large enough to ensure a ruby translucent effect [20].

From the fourteenth century, another process was used for unclear reasons, but perhaps related to changes in glass composition or a preference for a simpler, more reproducible, and less costly process. A gather of white glass was directly dipped in a pot of Cu-bearing glass so casing the clear glass before blowing. The cylinder formed was opened and heat treated to nucleate and grow the Cu nanoparticles in a 10–300 μm thick red coating (Figure 7b). This method subsequently developed into more sophisticated approaches such as blowing a thin bubble of colored glass and then a second thicker bubble of clear glass inside it, a process termed *flashing*. Such two- or even multilayered glasses might show color variations across a sheet that could be used by an artist to create an effect of light and shade. This effect could be enhanced by etching or grinding away sections of the glass to lighten the color in one area (Figure 8). Such techniques were used by later artists, for example, to create the whites of the eyes of a red demon. Occasionally, other colors, particularly the strong blue of cobalt, were treated in the same way.

4.3 Enamels

Enamels are colored glassy coatings deposited onto smooth surfaces (Chapter 10.6). Their use on clear white glass developed in seventeenth and eighteenth centuries when window glass attempted to replicate canvas painting. They were fired on and melted to a fully glassy, transparent state (Figure 9). Often, large painted rectangles were leaded together or mounted into a metal frame to create the finished window.

4.4 Painting

When leaded together to create an image, individual body-colored sheets have serious limitations in the detail that can be achieved. Painting dark lines onto the colored glass surface solved the problem simply by modulating the amount of transmitted light since the painted areas remained opaque after firing. Termed *grisaille*, the paints used were a compound of ground glass and metal-oxide black pigments (generally, iron oxides) mixed with carefully selected liquid binders to allow the buildup of successive layers prior to firing at around 600 °C or higher

Figure 8 Red flashing on a clear glass, etched away to give the detailed patterning of the costume, along with yellow and red stripes obtained from colored rods deposited on the base glass and drawn upon blowing. Weathering apparent at several places, in particular at the junctions with lead. for the image to become permanent (Figure 10). The firing furnace would take several hours to heat up and longer to cool. For this reason, and also to reduce the risk of fracture, the number of firings was kept at a minimum for any one piece of glass. This limited reaction time resulted in a significant chemical heterogeneity, the presence of voids, and thermal expansion mismatching, however, which makes this material bearing elements such as iron, manganese, and lead highly reactive and, thus, prone to corrosion (Figure 11).

This technique goes back almost as far as the use of a combination of colored pieces since indications of drawing have been found on sixth- and ninth-century fragments coming from buildings, excavated in Italy, France, and Germany [4, 5], some displaying recognizable religious images. From the latter period there is also written evidence of such pictures according to descriptions of

Figure 9 A large fire drawn with *sanguine*, a thin red to warm brown enamel made from hematite and other iron oxides melted with a flux on the glass surface. pilgrims traveling in Europe [5]. Dating back 900 years, the earliest surviving examples are in the aforementioned Augsburg Cathedral, but their high quality suggests that the tradition of glass painting was already well established.

Although the style of painting and decorative techniques evolved over the centuries, the basics have remained unchanged [21, 22]. Application of paint by a smear technique was the earliest, followed from about 1300 by stippling with a long hog hair brush, and later by the use of badger-hair brushes for smoothing the paint to an even finish (*badgering*). All these techniques served for modeling and were usually applied onto what would become the interior surface of the window although the paint could also be applied to the reverse of the glass for special effects. Trace lines provide basic outlines and shapes, for drapery, hair, faces, etc. For highlights, stickwork cut back through the paint layers to the base glass.

4.5 Silver Staining

As introduced from the early fourteenth century, an easier method producing a yellow hue on a single sheet of clear glass was silver staining. The technique was

Figure 10 Grisaille work in a sixteenth-century panel from a church in Chartres destroyed during the French revolution, which is now exhibited at the Centre International du Vitrail in Chartres. Source: Photo P. Richet © C.I.V.

similar to that developed for luster pottery by Abbasids potters at Baghdad and Samarra during ninth century, some records suggesting that it already existed in the Roman/Byzantium Empire [23]. This development was accompanied by a significant growth in the output of decorative glass. A stain made up of clay or Venice turpentine containing silver compounds such as the nitrate, chloride, or sulphate is deposited on areas of the image such as the braiding of a rich costume, the halo around the face of a saint, or a golden crown where a yellow color was appropriate (Figures 12 and 13). The concentration of silver metal precipitated in the glass is limited by the glass composition (redox ions present) so only low concentrations of silver in the stain are needed. To deepen the color, up to three or four painting and firing cycles may be used to increase the depth of penetration; and so to control the shade of color produced, which can range from straw yellow to dark orange. To avoid the use of extra leading, the same process carried out on a blue glass may produce the

green color, for instance, needed to represent foliage (Figure 13).

Upon firing, four successive steps have been distinguished [23]: (i) penetration of Ag^+ within the glass through exchange with alkali ions; (ii) diffusion of Ag^+ deeper below the glass surface as determined by Fick’s law; (iii) reduction of Ag^+ into Ag^0 either by oxidation of Fe^{2+} or other ions or by reaction with non-bridging oxygens; (iv) aggregation of insoluble Ag^0 into silver nanoparticles, which may themselves coalesce. Staining is carried out below the transformation temperature of the glass

Figure 13 The smart integration of thin leading to delineate tree trunks: details of the heavily restored sixteenth-century stained glass window depicting Abraham and Melchizedek in Sainte-Foy church, Conches-en-Ouche (Normandy, France). Silver staining at the bottom. *Source:* Photo P. Richet.

and at a lower temperature than that needed for firing on paints. At higher temperatures, some silver can diffuse back to the surface creating a reflective layer. Staining is, therefore, the last process to be undertaken in creating an image. The color obtained and its uniformity markedly depend on the starting silver salt and firing temperature: an intense color is, for instance, obtained with AgNO_3 and Ag_2SO_4 fired at lower temperatures, but is homogeneous with the former salt and not with the latter [24].

5 Leading

The production of a stained glass window begins with a drawn image incorporating lead lines. In medieval times, this would have been done on a whitewashed table of

which the fourteenth-century Gerona table is a surviving example [5]; as paper became more available and its cost fell, a full-size image or “cartoon” would have been drawn on this medium. Pieces of glass were cut to the shapes and the artist, who may or may not have been the designer, then paints the detail on the blank glass, following the lines on the drawing. These cartoons were often reused, sometimes reversed. Some stained glass designs were inspired by or copied from printed sources or canvas painting; some firms maintained a pattern book as a basis for their creations.

Initially, glass windows were set in frames of wood, plaster, or even bronze. As the images increased in complexity, ways of assembling multiple pieces of glass into a stable structure were needed. To hold different sheets together, the method adopted over many centuries has been to use a lead strip, termed *came* (from the Latin *calmus*, reed), with an H profile. Not only does lead have the advantage of melting at the low temperature of 327 °C, but it is a soft material that deforms readily and, thus, adjusts to the shape of the glass panes while preventing stress from accumulating at their edges. The original comes were probably made by pouring molten lead between parallel reed stems on top of sand contained in a bottomless wooden box. Upon casting, the reed stems burnt away, leaving a flat slab of lead containing parallel holes. Cutting along the holes with a knife finally yielded an “H” section strip of lead. From the seventeenth century, the came has been obtained more directly by extrusion with a full width that now ranges from as little to 2 mm for subsidiary lead lines to 20 mm, 6 mm being the norm for the main lines. Alternatively, the came profile can be square but bending them is more difficult than with a convex profile.

Leading highlights the outline of the image being created. It has always been carefully integrated into the image design, sometimes in the form of thin lines (Figure 13). In this respect, its role is similar to that of the painted lines used by the artists. Although a key development in the technology of stained glass, its origins are unclear. One pointer is that scraps of lead have been found with glass fragments from Roman buildings in both Germany and France. An early development in producing decorative designs with this technique was the use of glass quarries, square- or diamond-shaped pieces of single- or multicolored panes assembled into diagonal lines in patterns that have remained in use to this day. This technique allowed large areas to be glazed with the small panes that could be easily made from crown glass.

To create an image, the individual glass sheets had to be cut first into more complex shapes. The glazier had several tools at his disposal, which have not changed much over the millennium. The medieval glazier broke the

Figure 14 Restoration of an English fourteenth-century stained glass window in the parish church of Wycliffe, St Mary the Virgin (Diocese of Leeds) after a catastrophic fire. Individual fragments assembled after cleaning, ready for leading. *Source:* Photo John and Ruth Cooke.

sheets into smaller sections with a red-hot iron. Finer detail was obtained with a grozing tool, pliers, or a simple strip of metal with a square notch at one end to grip the edge of the glass and “nibble” away small fragments of material. The glass-cutter with a small rotating wheel of a hard mineral (nowadays steel or tungsten) is a relatively modern development. Diamond cutters have also been used to score the glass for initial shaping.

Cutting the colored sheets was facilitated by a life-size cartoon depicting the intended image. Once each piece was completed, it was laid out on the glazing bench (Figure 14), the leading was added, and finally joins in the came were soldered into place to create a water-tight window. Actually, the leading itself was part of the overall design of the picture, serving in particular to separate differently colored sheets (Figure 13). The glazed and leaded panels had then be installed, supported by a configuration of stanchions and horizontal wrought iron

Figure 15 Exterior view of a thirteenth-century stained glass depicting Christ's Passion in the choir of the Sainte-Chapelle, in Paris, held in place by *ferramenta*. Panel not cleaned, having kept the patina (mixture of gypsum and oil + dust) deposited at the time of the restoration made between 1846 and 1855 by F. Duban, J.-B. Lassus, and E. Boeswillwald. *Source:* Photo Philippe Colomban.

bars, or *ferramenta*, built into the surrounding masonry (Figure 15), but also generally visible from the interior (e.g. Figures 2–8).

6 Later Trends: Nineteenth to Twentieth Century

Following a period of relative dormancy, the renaissance of Gothic Architecture in the eighteenth–nineteenth century created a revival in stained glass windows especially in England where the 1818 *Church Building Act* resulted in the construction of about 600 churches in the new urban centers that were rapidly expanding. Many of the artistic effects/glass technological developments that had peaked in the Middle Ages had to be reinvented. But the continuous increase achieved in the meantime in glass quality was in itself problematic because advantage could no longer be taken of defects to produce special effects such as the scattering of light by tiny air bubbles. One-time director of the Chance Brothers glass-making company, Georges Bontemps (1799–1883) was one of the foremost pioneers in the reconstitution of ancient processes (Chapter 10.9) but his own work in stained glass was definitively in the new, distinctive style of the nineteenth century (Figure 16).

Figure 16 The prophets Joel and Amos of the Old Testament pictured by the famous glassmaker Georges Bontemps (Chapter 10.9) in the basilica Notre-Dame de Bonsecours, near Rouen. Hues much darker in the nineteenth century than in the Middle Ages. *Source:* Photo Danielle Velde.

In a context where a high level of artistry had been regained, the period was in parallel characterized by increasing experimentation in glassmaking for decorative purposes. The situation created significant tensions in that the church, which still remained a major patron of the field, often had an approach limited by the constraints of a past grounded in Gothic Architecture (Figures 16 and 17). The Arts and Crafts movement generated a desire to return glassmaking to its early roots. Consequently, another method of making sheets used by the Romans was reintroduced in 1889. The approach was to blow a square bottle and then use the sidewalls and base as sheet glass. A characteristic of this product was that the middle of each face was much thicker than the edges. Sheets were sold as *Prior's Early English* or *Norman* slab glass and were often brightly colored.

In England, the influence of Augustus and Charles Pugin was very important in the 1830s. Great effort went into the methodologies for making suitable sheet glass. Several firms arose throughout Europe to reproduce the earlier techniques. For example, in the United Kingdom in the 1840s, Winston used chemical analysis in an attempt to uncover the secrets of medieval windows. A key firm in the United Kingdom was James Powell and Sons of Whitefriars Glassworks in London. The

Figure 17 Late nineteenth-century stained glass from Christ Church, Eccleston, St Helens, created by the famous Hardman studio in Birmingham in 1885, which became well known in 1838 when it was commissioned to make the ornamental metalwork of the new Houses of Parliament in London. Source: Photo David Martlew.

output of such firms was used both in the restoration of much older stained glass and the creation of new windows for the rapidly expanding number of churches during the nineteenth century with architecture influenced by the Gothic Revival. These artists though were willing to adopt new approaches not widely used previously such as the acid etching of flashed glass or adding colored glass to provide surface texture [25]. Artists thus obtained special effects by combining the newly rediscovered ancient techniques with processes used in other fields, such as the porcelain transfer printing or with the wholly new invention of photographic impression [26].

During the same period, the Americans made a particular contribution to the decorative glass market by applying similar techniques to lamp shades and similar items. The most famous of these was Louis Comfort Tiffany (1848–1933). By mixing several different colored glasses into one sheet and adding small fragments of colored glass to white glass, he created a wide range of impressive optical effects, which became very popular. These were assembled in the same manner as traditional stained glass, substituting copper foil for lead came.

The early twentieth century also saw a step change in the artistic world as a revolt against the strict formalism of earlier years, which gave rise to the Art Nouveau movement. As exemplified by CdS–CdSe solid solutions, the discovery of new pigments allowed a vivid coloration to be combined with a high luminosity for color ranging from yellow to red [27]. Controlled nucleation of these new semiconductor nanoparticles upon processing of the glass piece thus replaced the ancient techniques based on silver and copper metal nanoparticles.

These new processes spilled over into stained glass in part because many eminent artists like Jacques Grüber (1870–1936) were commissioned to create decorated glass windows. Images were increasingly influenced by nature with its inherent colors and curves. As glass art ceased to be primarily the domain of the church, the images created became increasingly secular in content. Many artists, for example, Charles Rennie Mackintosh (1868–1928) in Glasgow, introduced more abstract designs while other famous artists such as the painters Henri Matisse (1869–1954) and Marc Chagall (1887–1985) also committed themselves to stained glass.

More recently, several new approaches have been used at the same time as glass art expanded into new directions. These rely, for instance, on *Dalles de verre* (Glass slabs) or combinations of different industrially produced clear and patterned glasses, an example being slabs up to 5-cm thick whose varying texture makes it possible to use them unpainted in the creation of giant mosaics. Cement or resins replaces the leading used earlier to hold the pieces together (Figure 18). Modern developments in cutting technologies with water jets or laser beams has allowed the production of complex shapes that can be joined simply and accurately along their edges by modern adhesives, for example, UV-cured resins. This method allows images to be produced without leading; the resins can, however, discolor under the action of UV light over longer periods. Another approach is in effect to create a collage by joining or fusing colored and clear sheets together. It is even possible to use coarse powdered glass remelted at relatively low temperatures in the *Pâte de verre* (Glass paste) technique to keep air bubbles and other heterogeneities as decorative elements (Figure 18).

Production technologies have also changed dramatically (Chapters 1.4 and 10.9). From the early twentieth century, machine-drawn glass sheets displaced the old cylinder- and crown-glass production for many architectural applications. The earlier Fourcault process was supplanted by the Coburn process in the 1920s, but the best was the PPG Pennavon process invented in America and perfected by Pilkington in 1933 (Chapter 1.4). Now, float glass is the dominant product on the market. Such glass lacks the optical variability of earlier products, giving almost perfect reflections and transmitted images; many

Figure 18 Stained glass made from *Pâte de verre* panels held by cement (d. 133 cm): Christ and the children pictured in 1934 by François Décorchemont (1880–1971) for the Sainte-Foy school of Conches-en-Ouche (Normandy). Source: Photo Musée du verre de Conches/Siloé, courtesy Éric Louet (inv. MV.1993.1.1).

would argue that something has been lost and certainly such products cannot be used for repairing ancient windows. However, one approach that has been used with some considerable success is to add engraved images to such sheets as a new way of creating decorative windows.

7 Conservation

Corrosion is not a new concern for glass (Chapters 5.11 and 5.12). The sand used as a raw material by early glassmakers in the Levant had adventitious concentrations of calcium oxide from sea shells, which ensured the stability of their products. As a flux, naturally occurring alkali-rich material such as the natron found in Wadi Natrun was particularly appropriate (Chapter 10.3) and traded for making other commodities such as dyes or unguents. After the Roman times, the “Alexandrian” glass made with this flux was no longer available in Europe where the ashes of plants growing in maritime environments, such as *salicornia*, became used as a flux after concentration by washing and evaporation. These soda glasses with added lime were relatively durable so that ninth-century window glass excavated from an early site in Jarrow, Northumberland, United Kingdom, still retains its translucency.

As they moved inland during the first millennium, glassmakers turned to the ash of trees as a fluxing agent, ending up with compositions much richer in potassium (Table 2). For example, Theophilus’ writing in the twelfth century [9] recommended the ashes of beech wood;

bracken was also used. Accounting for more than half the production by the thirteenth century, these potash (*pot ash*) glasses were less chemically durable than soda glasses so that they have survived less well in stained glass windows. Corrosion mechanisms and conservation are consequently significant issues [3, 4]. The problem can be real even for twentieth-century windows; when cement was used in place of lead to assemble the panes, the *basic* environment caused corrosion (Chapter 5.11).

Corrosion typically results in the pitting of the outside surface but can also be significant on the inside of the pane where condensation and evaporation cycles occur, the first drawing out the alkali from the glass and the second concentrating it to produce a strongly alkaline environment, which is particularly detrimental to the glass surface (Chapter 5.11). Enamels that are insufficiently durable can also result in loss of detail over time. Modern conservation aims at reducing this cycle by means of internally ventilated environmental glazing systems whereby the historic glass is protected by a layer of protective glazing and the interspace is vented to the inside [17].

Over the centuries, accidents, fires, and wars have obviously been in many ways more effective in causing damage or destroying stained glass than corrosion by water or animal excreta. Another insidious source of degradation is the displacement of rigid stone frameworks built on clay bedrock that are induced by seasonal changes of the groundwater level and cannot always be accommodated by the lead comes. Upon simple breakage, the easiest way to fix the damage was to add some leading (Figure 19). When destruction was more severe, complete panels were often replaced in the nineteenth century by new stained glass that may look so similar to the original (Figure 11) when templates and detailed drawings were available that distinguishing ancient from recent work can be difficult. The huge optical absorption of Cu nanoparticles particularly caused difficulties in nineteenth-century restoration of medieval stained glass. Replicas of red glasses consisted of a thin red layer covering an optically clear plate (Figure 7b), which was then etched with HF to mimic the heterogeneous nature of medieval pieces (Figure 7a).

Since it has to be replaced roughly every 100–150 years, the leading fails long before the glass. This event allows for some cleaning of the glass and any necessary restoration. Old windows must also be cleaned. An important debate has been the extent to which cleaning and repair should include repainting of images. Over the years, some such restorations, particularly if they have occurred after a catastrophic event such as a fire, may have resulted in confused images. The use of computer technology has facilitated the re-creation of such pictures in the way one would tackle a jigsaw.

Figure 19 An ancient, obvious repair at the head of an apostle in a sixteenth-century panel from a church in Chartres destroyed during the French Revolution, which is now exhibited at the *Centre International du Vitrail* in Chartres. Source: Photo P. Richet © C.I.V.

Stained glass windows, particularly the old ones that need repair, used lead that also contained not only trace amounts of copper or tin but also of potentially dangerous impurities like antimony. Paints and glass colorants contained a variety of toxic materials so that abrading glass creates a dust hazard; acid etching also involves hazardous materials. Hence, all new projects and any restoration work must be undertaken with the associated risks in mind. A useful guidebook has been written on this subject [28].

8 Perspectives

At all periods, stained glass has not been an art in itself but a key ingredient of monumental art. Whereas it was designed to highlight the beauty and harmony of the building in which it was installed, in return the building architecture was designed to give it a privileged place.

With a style that evolved throughout the ages and perhaps reached a formal apex in the sixteenth century when all the technical resources of painting on glass had been mastered, it benefited from new forms of expressions after the eclipse of the seventeenth and eighteenth centuries. As in other branches of the art community, stained glass artists continue to develop new styles and techniques in line with the increasing secularization of their audience and to apply their skills ever more widely in the domestic context. Imaginative abstract images are much more common and even in religious settings designs have been influenced by movements such as cubism and expressionism; the church in France has been particularly open to contemporary designs as exemplified by the romanesque basilica Saint-Julien in Brioude (French Massif Central) recently adorned with new stained glass made by the Korean master Kim En Joong (b. 1940) [29]. New techniques are being developed and old ones reinvented to suit the use of stained glass in new architectural situations such as shopping arcades and for the smaller commissions that are now often the bread-and-butter of the trade [4, 29].

At the same time, the preservation, renovation, and conservation of ancient glass panes form a significant part of the activity of stained glass artists. Accurately reproducing the color and surface texture of old windows imposes its own requirements on them and requires a deep understanding of ancient methodologies in this field. The stakes are especially high as the extant stained glass windows represent but a tiny fraction of those that were originally installed. The destructions wrought by the two world wars are of course familiar, but the massive losses throughout the ages caused by civil wars or the dissolution of monasteries at the time of the Reformation are not so well known.

Of course, the progress made in the last decades in both glass science and analytical methods is being put to good use to investigate the effects of long-term exposure to the atmosphere [30] and atmospheric pollution as well as to determine more accurately the history of the material [14]. At the thirteenth-century Sainte-Chapelle in Paris (Figure 19), portable Raman spectrometry (Chapter 2.2) has, for instance, proven to be a valuable tool to distinguish on site the original 13th material from the glass repairs made in the nineteenth century [13]. Because the high-frequency Si–O vibrations are sensitive functions of the network modifiers present, it is, for instance, possible to distinguish Ca-rich Na-bearing, mixed Na, Ca, and K-rich glasses.

Interestingly, the conclusions derived can be inconsistent with those recently drawn from visual inspection, which is not so surprising since the nineteenth-century restorers had been competitively selected on the basis of their ability to duplicate original stained glass panels

Figure 20 Raman spectroscopy in the service of ancient stained glass: on-site nondestructive measurements made in the Sainte-Chapelle in Paris. Remote optical head mounted on a XYZ stage precise to within 1 μm and connected by optical fibers to an air-cooled green laser and to the engraved prism spectrometer and its CCD detector. Original windows from the thirteenth century picturing Saint John the Baptist and the Book of Daniel, heavily damaged at the bottom during and after the 1789 French Revolution, and restored in a nondocumented way between 1846 and 1855 with either replicas or original pieces taken from the top. Source: Photo Philippe Colombar.

[31]. That medieval techniques were then mastered suggests that glass characterization is needed to determine unambiguously the origin of stained glass when the existence of repairs is known historically. In addition, observations made on the external sides of the panels can give misleading information on ages because surface weathering causes a significant decrease of spectral intensities [32].

As for accurate chemical analyses of the original Sainte-Chapelle glasses, they have revealed that two different sources were used in the same windows, probably because of the unusually high amounts of glass needed to be produced in a short time interval (Figure 20).

Interestingly, both glasses were made near Paris from the same plant ashes but one of them has a typical “Norman” composition characterized by higher Na_2O and MgO contents, which indicates the hiring of Norman masters who were able to add small amounts of NaCl to the batch to lower melting temperatures [15].

If stained glass has much benefited from the advances made in materials science, the reverse is also true, thanks to fragments excavated in generally well-defined contexts. Since these samples differ by their chemical compositions and have been subject to corrosion over many centuries, they represent valuable model systems to determine the long-term stability of glasses under natural conditions. Applications of these studies have thus been made to glasses used to store waste, particularly radioactive material [33].

Acknowledgments

Warm thanks are due to Philippe Colombar for most valuable suggestions, to Hervé Alfonsi, Philippe Colombar, Jonathan and Ruth Cooke, Eric Louet, David Martlew, Pascal Richet, and Danielle Velde for generously providing stained glass pictures, and to Jean-François Lagier for the permission to reproduce pieces exhibited at the Centre International du Vitrail in Chartres.

Furnaces and Glassmaking Processes: From Ancient Tradition to Modernity

Marie-Hélène Chopinet¹ and Pascal Richet²

¹ Saint-Gobain Recherche, Aubervilliers, France

² Institut de Physique du Globe de Paris, Paris, France

1 Introduction

In the first centuries of our era, the importance of glass items in the households of the Roman Empire was such that it would remain unmatched until the seventeenth century. In antiquity, the large scale of some melting tanks – pulled down to recover the melted glass – is indeed well documented in the Levant from where glass was exported throughout the Roman world – and even beyond – either as finished products or as ingots to be shaped in small workshops (Chapter 10.3). Culminating with the invention of blowing and associated decorative techniques (Chapter 10.5), the glassmaking processes devised in antiquity then underwent little changes throughout the ages.

After the collapse of this well-managed system in the early Middle Ages [1], glass had to be made locally from the available raw materials, at a scale that was small by antiquity standards. The furnaces would remain small until the fifteenth century when a marked size increase allowed a number of glassblowers to work in parallel thanks to multiple working ports [2]. Far from the Near Oriental cradle of the industry, a major problem that restricted glassmaking was the lack of adequate local sources of alkali salts. The most convenient sources were the Na-rich ashes of salt-tolerant plants in the Mediterranean and the K-rich ashes of wood, fern, or bracken in Northern Europe, actually complex mixtures of carbonates and other salts that were bearing unwanted coloring elements (Chapter 10.11). For centuries, the so-called *forest glass* was made in local glasshouses with a crude design, greenish or brownish hues, mediocre quality,

and, thus, with walls that were thick and incorporating air bubbles, stones, or other defects.

In Venice, which would dominate the European glass world from the fifteenth to the seventeenth century thanks to the purification process applied to alkali salts, glass working appeared at the turn of the first millennium but significant production began only in the thirteenth (Chapter 10.7). That was the time when stained glass was already made throughout Europe, mainly for church windows, in small workshops with the crown and cylinder processes (Chapter 10.8). Along with economic expansion, further improvements in these processes and glass transparency led to the development of glazing in civil architecture from the fifteenth century. Glass was remaining expensive, however, so that in 1567, the Surveyor of the Duke of Northumberland recommended [3] that

in consequence of the extreme violence of the east winds, the glass of the windows of this and other of the Lord's Castles and Houses in this country do decay and waste, and it were desirable that the whole height of every window at the departure of the Lord, and during the Lord's absence, were taken down and laid up in safety, and at such time as the Lord or any other should lie at any of the said places, the same might be set up anew with small charge, where now the decay is very costly to be repaired.

Such recommendations were hitherto not uncommon, but they rapidly became unnecessary because panes of rapidly increasing sizes were produced at reduced prices, as particularly well exemplified by the large, permanent windows of the Versailles palace in the seventeenth century.

Technical improvements remained empirical in nature until the end of the following century, in particular when melting of the raw materials had to be changed in significant ways to cope with the replacement of wood by coal in furnaces. As the makers of telescopes and microscopes repeatedly complained, however, glass quality remained problematic for demanding applications because of the presence of bubbles, striae, streaks, veins, tails, and other defects caused by solid inclusions and the chemical variability of the raw materials, which could not be remedied by insufficient melting temperatures and chemical homogenization (Chapter 10.10). As a distant consequence of the Scientific Revolution, the situation began to change rapidly at the turn of the nineteenth century thanks to progress made in both chemistry and physics. The discovery of alkali and alkaline earth elements from soda, potash, lime, and magnesia would of course represent a major starting point to improve glass compositions and control them through quantitative analyses of the raw materials used (Chapter 10.11). Understanding of combustion mechanisms as reactions with oxygen, together with the advent of thermodynamics, and, in particular, the formulation of the notion of *energy* and of the Law of its conservation in the 1830s rapidly had also a strong impact on furnace design and, thus, on melting processes.

The quality of glass and production volumes have always critically depended on melting conditions. Hence, it is appropriate to begin this review with furnaces; the two main points of interest are ways in which higher and more homogeneously distributed temperatures have been progressively obtained and how the switch from pot to tank furnaces took place and eventually made continuous production possible from batch melting to the final glass object. Because plate glass had to be of unusually high quality, it fetched the highest prices and required special fabrication procedures that will be discussed next. Plain flat glass will in contrast be only briefly mentioned because the ancient crown and cylinder methods are described in Chapter 10.8 and the float and previous mechanical processes designed from the late nineteenth century in Chapters 1.4 and 9.6. At the other end of the market, attention will rather be paid to the fabrication of glass containers until the beginning of the twentieth century, the recent part of the story being told in Chapter 1.5. As for safety glass (Chapter 9.2) and fibers for either mechanical reinforcement (Chapter 1.6) or thermal insulation (Chapter 9.3), their production is too recent to be reviewed in this chapter. In preamble, however, it is useful to review the issue of the sources available to understand past processes.

2 The Written Sources

Like for antiquity, extant artifacts and archeological remains are the main sources of information on glassmaking in the Early Middle Ages in view of the lack of written sources for both periods. Although the ancient methods were still used for shaping glass (Figure 1), their first known descriptions date back to only the twelfth-century with the treatise *On Divers Arts* of the Benedictine monk Theophilus [5]. Along with glazing with plain or stained glass, different kinds of furnaces made of stone and clay were described at the beginning of Book II of this treatise. Whereas a large furnace, 15 ft in length and 10 ft in breadth, was divided into three parts for making glass, two slightly smaller ovens were specifically designed for cooling and for dilating and flattening it.

From the Renaissance, the ground is firmer thanks to two famous monographs that differed from Theophilus' work not so much by their technical content than by their woodcuts, which dramatically illustrated the importance of the new printing press for the diffusion of applied knowledge. These books were the *Pirotechnia* [6] of the Siennese metallurgist S. Vanoccio Biringuccio (1480–1539) and the *De Re metallica* [7] written with more detail in Saxony by the former physician Georgius Agricola (1494–1555). There were many reasons why glassmaking was dealt with in these two metallurgical treatises. An obvious one was that, as illustrated by Biringuccio and Agricola's plates, melting furnaces were actually strikingly similar in metallurgy and glassmaking. And not only was in addition glass akin to metals in natural philosophy (Chapter 10.4), but the term *metal* already used in Babylonian times by workers to designate the molten glass (Chapter 10.11) was still in use in the workshop [8] and would in fact remain so until at least the end of the nineteenth century.

It was only from the early seventeenth century that technical treatises especially devoted to glass were published. The most influential was the *Arte vetraria* [9] written in Florence by the priest Antonio Neri (1576–1614). This compilation of recipes for preparing and coloring glass, mostly Venetian, was written in the style of *book of secrets* at the request of the ruling Medici princes who were sharing with Neri a strong interest in alchemy and thought that the remarkable properties of glass were a key component of any attempt made at metal transmutation [8]. As a matter of fact, Neri's recipes were often obscure and addressed the needs not of ordinary glassmakers, but of "a small number of artists and highly skilled artisans engaged in the production of rare and expensive glassware for wealthy princes" [8]. When they translated Neri's book into English [10] and German [11], the physician, botanist, librarian, and founder Fellow of

Figure 1 Glassmaking as pictured in the *Pit of Memnon*, one of the plates of Ms. 21489, British Library, an early fifteenth Bohemian century manuscript illustrating the *Voyage d'Outremer* (the Holy Land), actually a compilation of previous accounts [4]. Except for the extraction of the raw material from a legendary inexhaustible pit at the top of the plate, the picture describes contemporary practice in Bohemia: blowing and marvering of the gob before a furnace made up of a melting compartment at the center and an annealing oven on the left, and heated with wood introduced through the opening at the bottom right.

the Royal Society Christopher Merrett (1614–1695) and the chemist Johannes Kunckel (1630–1703), respectively, complemented it with much additional material. For Merrett, who had been asked by the famous chemist Robert Boyle (1627–1691) to do the translation, like for Neri and Kunckel, glassmaking had been a kind of hobby,

which is probably why Agricola's woodcuts – and not original drawings – found directly their ways into their treatises.

Jean Haudicquer de Blancourt (b. ~1650) was in France an actual glassmaker. His *L'Art de la verrerie*, which also became a reference work at the very end of the

seventeenth century, borrowed also much from Neri while incorporating new recipes as well as alchemical speculations [12]. The fortune of Neri's book nonetheless kept going on in the eighteenth century since a French translation of the German edition, including Merrett's and Kunckel's additions, was published in 1752 by the German-born Paul-Henri Thiry, baron d'Holbach (1723–1789) [13]. Finally, a Spanish translation of this French version was then published as late as 1780 [14] at the request of the king Carlo the third (r. 1759–1788), 168 years after the original publication of Neri's treatise [15].

Although lacking in detail, early patents nonetheless constitute another useful source of information as illustrated by Ravenscroft's on *flint* glass (Chapter 10.10). As a matter of fact, much information on lead-bearing compositions had already been reported by Neri himself who stated, for instance, that the glass of lead "is the fairest and noblest glass of all others at this day made in the furnaces," or that "the pots and Lead must not have too much heat in the furnace neither must be the metal be wrought too hot" ([8], Chapter LXI). By far, however, the most accurate and comprehensive descriptions of all the facets of glassmaking and shaping were written by Antoine Allut (1743–1794) for the epoch-making *Encyclopédie* published by Denis Diderot (1713–1784) and Jean D'Alembert (1717–1783) [16], to which Holbach contributed heavily. Of special interest were the 169 large plates appended to the articles on glassmaking, which still represent the best reference about traditional methods and constitute an extremely rich iconographical resource that has since then been extensively mined (Figure 2).

By itself, the interest raised for so long by Neri's book attests to the slow pace at which glassmaking evolved during the seventeenth and eighteenth centuries. From the early nineteenth century, however, repeated advances resulted in a technical literature that began to include chemical analyses and became rapidly so large that it cannot be reviewed in any detail. Because some of their plates are reproduced in this chapter, only two influential treatises will be mentioned. The first is the rightly famous *Glass Maker's Guide* [17] written by Georges Bontemps (1799–1883), an engineer about whom a glassmaker from the Chance family said that "no one alive knew more than he about every branch of glass manufacture, whether in theory or in practice" [18]. From 1823 to 1847, Bontemps [19] actually directed the glass factory of Choisy-le-Roy, near Paris, and then from 1848 to 1856 the Chance Brothers company in Birmingham where he brought the know-how of the Guinand process for making homogeneous flint glass (Chapter 10.10). As for the second of these reference books [20], it is *Glass, Its History, Its Making* of the chemist Eugène Péligot (1811–1890) known among other achievements for his discovery of the uranium element.

Figure 2 Two aspects of late eighteenth-century glassmaking depicted by the *Encyclopédie* [12]. Fig. 2: The hardship of the craft; the loading of a big melting pot into the furnace by workers turning their back on the fire and protected from the heat by two wet carter's smocks stuffed with straw and clay and wearing double hats also filled with clay. Fig. 7: The working tools of the glassmaker; from left to right, shears (the Roman *forfex*), scissors, and four kinds of tongs (scale in feet).

For later periods and, in particular, the development of mechanization in the various branches of glassmaking, the studies published by Michael Cable (1934–2016) will provide readers with much more detailed accounts than could be presented here [21–24]. Particularly interesting are the blueprints of numerous machines included in these papers, which allow their evolution to be tracked down step by step.

3 Furnaces

3.1 Traditional

As stated by Agricola [7], "some glass-makers use three furnaces, others two, others only one. Those who use three melt the material in the first, re-melt it in the second, and in the third they cool the glowing glass

vessels and other articles.” Reporting the respective sizes of these different furnaces, which were typically from 6 to 10 ft wide and up to 8 ft high (Figure 3), Agricola explained that

Of these, the first furnace must be vaulted and similar to an oven. In the upper chamber [...], the mixed materials are heated by a fierce fire of dry wood until they melt and are converted into a vitreous mass. And if they are not satisfactorily purified from dross, they are taken out and cooled and broken into pieces; and the vitreous pieces are heated in pots of the same furnace.

The second furnace is round [...] on the outside, so that it may be stronger, it is encompassed by five arches [...]; it consists in a like manner of two chambers, of which the lower one is vaulted [...]. In front this chamber has a narrow mouth through which the wood can be put into the hearth, which is on the ground. At the top and in the middle of the vault, there is a large round hole which opens to the upper chamber, so that the flames can penetrate into it. Between the arches in the walls of the upper chamber are eight windows, so large that the big-bellied pots may be placed through them on the floor of the chamber, around the large hole. [...]. In the back of the furnace is a rectangular hole [...] through which the heat penetrates into a third furnace which adjoins it.

The third furnace is rectangular [...]; it also consists of two chambers, of which the lower has a mouth in front, so that firewood may be placed on the earth which is on the ground. On each side of this opening in the wall of the lower chamber is a recess for oblong earthenware receptacles [...]. The upper chamber has two holes, one on the right side, the other on the left, of such height and width that earthenware receptacles may be conveniently placed in them. [...] In these receptacles the glass articles are placed so that they may cool in a milder temperature; if they were not cooled slowly they would burst asunder. When the vessels are taken from the upper chamber, they are immediately placed in the receptacles to cool.

Operations were of course more complicated when two furnaces, or only one, were available: from melting and blowing to annealing, a rigorous day/night schedule then had to be followed to optimize furnace use and wood consumption. Furnaces were built with unfired, but dried clay bricks, a highly technical process, but none lasted more than a few weeks before having to be rebuilt. This type of melting furnace would be used with only minor modifications until the seventeenth century [17]. The main

(b) The working and annealing furnaces; A: arches of the working furnace; B: mouth of the lower chamber; C: windows of the upper chamber; D: big-bellied pots; E: mouth of the annealing furnace; F: recesses for the receptacles; G: openings in the upper chamber; H: oblong receptacles.

goal of glassmakers was to increase lifetime through proper choice of clay and design improvement whereas melting temperatures slowly increased thanks to a better knowledge of the heating properties of wood and of ways to improve combustion.

The pots were also made of clay from which heterogeneous parts and fragments of pyrite, limestone, gypsum, or vitrifying matter were carefully removed. Making them required much skill as their breakage and ensuing glass leaks within the furnace was a very serious and costly accident. Of particular importance was the fact that melting had to be carried out in two steps to obtain a glass of satisfactory quality and limit high-temperature corrosion of the melting pots [17]. Under progressively higher temperatures, the first step was aiming at burning charcoal leftovers, eliminating humidity, and other volatile substances, and beginning the decarbonation process to produce a partially melted product named *frit*. The frit, to which the relevant metal oxides were generally added for colored products, was then melted without suffering from settling of the sand in the less dense molten alkali salt that first formed readily. The process would be applied until the nineteenth century to produce containers from very “difficult” types of glasses.

3.2 Reverberatory

The *reverberatory* (from the Latin *re-verberare*, to strike back) furnace (Figure 4) was not a brand new invention when it was first described in Biringuccio’s *Pirotechnia* [6]. Its original feature was to keep the wood fuel and the material to be melted separate. The latter was thus not in contact with the flames or deleterious fumes, but melted instead by the intense heat accumulated and radiated by the vault of the chamber.

Toward the end of the sixteenth century, shortage of wood began to be a serious issue in England where both glass- and steelmakers were badly needing the resource at a time when fierce competition was taking place between glasshouses, fostered by the flight of religious refugees from Northern Europe who had glassmaking expertise [25]. Interest in coal furnaces thus developed rapidly so

that a first patent valid for 21 years was granted in 1610 for the building of coal furnaces for a wide range of products. This goal was too ambitious so that a new patent restricted to glassmaking was granted the following year to a group of investors, who were quickly successful since glass was actually produced in 1612 at Winchester House in Southwark. In the midst of much litigation before the Privy Council, not only were the use of wood furnaces and import of foreign glass prohibited in 1614 but the *Proclamation touching Glass* issued on 23 May 1615 by the king James I (r. 1603–1625) then eventually forbade in England and Wales anyone to “melt, make, or cause to be melted or made, any kind, forme or fashion of Glass or Glasses whatsoever, with Timber of wood.”

The replacement of wood by coal implied important changes on the design of furnaces, however, because deleterious fumes from the smoke colored the glass exposed to the fire and prevented blowers from working before traditional openings. In addition, stronger drafts had to be used to whip up a hotter blaze. In the new furnaces, a long, underground tunnel fed air from outside the glasshouse to the grate at its center. The vault itself was built as a curved *crown* reflecting the heat accumulated from the fire toward the pots that were set around the waist of the furnace on a circular course of brickwork. The pots were covered for protection against soot, smoke, and black drops that fell from the crown. In British window-glass factories, the outer building was frequently of the same shape as the furnace itself, but not in continental glass factories. From this time on, glassmakers sought sites for their furnaces in places where coal was either mined or readily available by boat, which was a major change in their preoccupations. Thanks to the higher temperatures achieved, however, stronger glass could be made, in particular for bottles. But the change from wood to coal took place slowly in France, for example, where only from the

Figure 4 The earliest known representation of a reverberatory furnace in Biringuccio’s *Pirotechnia* [6].

early eighteenth century did bottles become fit to hold effervescent beverages thanks to increases and decreases in the proportions of sand and alkali salts, respectively, made possible by the higher melting temperatures [26].

3.3 Regenerative

As already alluded to, the fundamental advances brought by an understanding of combustion mechanisms and the formulation of the First Law of thermodynamics had important industrial implications when it was understood that heat engines were transforming into useful mechanical work much less than 10% of the energy of combustion of the fuel. An *economizer* was thus early designed by the Scottish clergyman Robert Stirling (1790–1878) for retrieving part of the heat lost to the condenser of his *air engine*. Following in his footsteps, the German-born engineer Carl Wilhelm Siemens (1823–1889), who became known as William, was first involved in 1847 in the design of an engine working with superheated steam whose condenser was supplied with regenerators. The engine was not a complete success so that, with his brother Friedrich (1826–1904) who had come to work with him in England, William turned his attention to simpler problems not involving complex mechanical devices. Such a more readily tractable question was the recovery of part of the energy wasted in industrial furnaces for heating not only the oxygen needed by the combustion reaction but also the nitrogen of the air. The idea was thus to use the huge amount of heat lost up the chimney to preheat these gases to improve energy efficiency. The process was patented in England in 1857 by Frederick for all kinds of industrial furnaces [27]. Its purpose was to let the combustion products

pass over an extended surface of brick, metal, or other suitable material, imparting heat thereto, which heat serves to heat the atmospheric air or other materials of combustion in such manner that the cold air or gases are first brought into contact with the less heated material nearest the chimney, and is brought by degrees into contact with the more intensely heated portions, until it finally passes over that portion of the said surface nearest the place of combustion.

A chamber full of bricks stacked in such a way as to leave as many interstices as possible between them was thus placed between the furnace and the chimney [27]. The burnt gases exchanged their heat with the chamber, cooling down when progressing toward the chimney. After a period of half an hour, for example, the chimney was shut up to let external air enter the hot chamber to be heated up in order to reach the combustion chamber of the

furnace at an already high temperature. At the same time, the exhaust gases were brought into similar chambers for the same period of time before the valves' openings were reversed (Figure 5). Not only was the heat efficiency much enhanced but the higher melting temperatures reached were favorable to the homogeneity of the glass whose quality was thus notably improved. The batch was still melted in clay pots, which were generally smaller at the bottom than at the top to promote regular heat diffusion (Figure 6). Their capacity was typically 400 kg for window and goblet glass in France and Belgium, but of only 75–150 kg in Germany and of up to 2500 kg in England [17].

In contrast to the traditional furnaces, however, the new regenerative ones required very skilled workers to be operated and they much suffered from ash deposition in their checkworks of refractory bricks. The solution found to this serious practical problem was to replace the solid by a gas fuel, which could also be preheated to increase further the heat efficiency. With a first report dating back to the seventeenth century and real industrial production for lighting in the early nineteenth [28], gasification of coal had long been well known when it was then put to use for furnace heating. On 22 January 1861, a new British patent was granted to the Siemens brothers to use a gas mixture of H_2 and CO known as *water gas* prepared in a *gas producer* (Figure 7) by the

Figure 5 Siemens regenerative pot furnace (width: 6 m): cross section through the furnace (a) and the four regenerators (b) [17]. Open arrays of bricks: d; Pots: X.

Figure 6 The open and closed clay pots still used in the middle of the nineteenth century [20].

reaction of steam with coke. At the basis of the process was the exothermic reaction

whose efficiency was improved if steam was blown onto the red-hot coal to produce hydrogen according to:

The water gas produced was actually a complex gaseous mixture in which, not surprisingly, nitrogen was predominating. Compositions of 24.2 vol % CO, 8.2% H₂, 2.2% CH₄, 4.2% CO₂, and 61.2% N₂ were, for instance, later reported at Saint-Gobain [29].

In addition to fuel savings up to 50%, advantages were the possibility of using lower-quality coal, a greatly increased operational facility, a more complete combustion reaction, and, thus, an almost lack of smoke, which was another important asset for making glasses of specially high quality, for example, for optical lighthouse lenses. In England, the first regenerative glass furnaces were built in Rotherham and Birmingham. The advantages of these new furnaces were such that many were already in use, in construction or ordered in Europe only two years later [30]. They included now four at Chance Brothers and Co in Birmingham (more being built), two in Dresden for Siemens and Mehlis, one in Glasgow for Stevenson & Co, two near Hamburg for Broederson & Co for sheet and container glass, two in Montluçon glass-works (central France), five at Saint-Gobain (five more ordered), and two for the British Plate Glass works, near St Helens in England, for plate glass and several for crystal glass or metallurgy.

As an example, the new 16-pot gas-regenerative furnace built by Saint-Gobain in its Glacerie of Cirey in 1864 produced 5793 m² of plate glass in 33 castings and consumed only 48 kg of coal per square meter of plate glass, representing a 50% savings on fuel consumption [29]. Initially, many features of traditional furnaces were of course retained. The burners were, for instance, set in the sieve where the pots were lying and where the grates separating the chamber from the hearth were previously placed so that air and the combustion gas were still admitted vertically. Progressively, further modifications were thus made to increase heating homogeneity via changes in the geometry and distribution of the burners so that batches were melted at the same rate in all pots. As cooled from the bottom by air circulation, furnaces had a lifetime of 16–18 months.

3.4 Radiative

In all types of furnaces hitherto designed, it had been considered that bringing the flame in very close contact with the batch was necessary to achieve efficient melting. Back in Germany in 1864 to take over a family glasshouse in Dresden after the death of another of his brothers, Friedrich Siemens thus signaled an important conceptual change when, reflecting on the nature of heat, he concluded that “combustion can only be perfect, and be maintained perfect, if the space in which it takes place is sufficiently large to allow the gases to combine out of contact with solid materials.” This condition implied that the “flame must not be allowed to impinge upon bodies to be heated, but must simply heat the bodies by radiation, and furnaces must be so constructed as to allow to the flame out of contact, not only with the substance on its bed, but with the walls and roof of the furnace itself” [31].

In these large furnaces, one reduced the production of soot by contact of the flame with colder surfaces by placing the gas and air inlets at a small distance of the crown of the heating chamber, and also of its walls, so as to leave a large space available for burning and flame development. Enough space had also to be left between the pots to ensure an even radiative heating. Large fuel savings could be made in this way, indirect additional advantages being in many cases an increased yield, higher glass quality, and an extended lifetime for the pots. These innovations would in fact pave the way to the tank furnace. Other configurations were nonetheless experimented. The gas-producing unit was, for example, installed close to the furnace itself and the regenerator used only for the air, the gas being directly injected into the furnace without being heated. The new furnace was much smaller, usually half the previous one, and thus cheaper to build but was operating with only 25–30% fuel savings (Figure 8).

Figure 8 The mutual disposition of Siemens furnace, gas producer, and regenerator [32].

In 1893, a comparison made between the traditional furnaces with burners in the sieve and the new ones with burners in the wall showed that the glass was of a much better quality when melted in radiation pot furnaces, but also that the crown was attacked because its height was too low [33]. Following furnace modifications at Saint-Gobain, it was concluded three years later that burners were more advantageous when placed in walls even though their fuel consumption was not lower [33]. After a slow start, these burners made operating conditions more regular because of the large amounts of heat stored in the refractory materials. In addition, they were easily accessible and easier to maintain; the crown was less attacked and the regenerative chambers were more durable thanks to decreased deposits; as for the pots, they were less violently attacked and, thus, more uniformly heated. True, the older furnaces could also ensure good glass quality but only for the initial periods during which combustion was optimal, which did not last long.

3.5 A Revolution: The Regenerative Tank Furnaces

When designing the tank furnace, engineers did not know that they were not breaking completely new ground, but rather much improving a concept already adumbrated in antiquity (Chapter 10.3). Originally, the Siemens brothers were not yet sure whether they might use real *tanks* without pots, but they readily solved the various problems caused by inadequate refractory blocks. Pots did vanish from the scene (Figure 9). In a design patented in 1872 [35], the tank was partitioned in three compartments

arranged to communicate with each other in a manner that the raw material is introduced and melted down in the one compartment, from the

Figure 9 From blueprint to actual construction, the new tank furnace with a deep melting area. (a) Siemens patent [34]; A: cave with the regenerative chambers B for air and C for gas; D: tank 18 in. in depth; E and F: “flues conveying the heated air and gas up from the regenerating chambers on one side, while the products of combustion pass down by corresponding flues to regenerative chambers on the other side” in a movement alternated from time to time. lower part of which the melted material is caused to flow into the top of the next compartment, whence it passes into the bottom of the third compartment, from which it is worked out.

As summarized in a subsequent patent [34], “no time was lost in cooling and settling the metal and reheating the furnace,” whereas “the tank was rendered more durable by being subjected to a uniform temperature and an economy in labor was effected in lessening the number of workmen required for the melting operations.”

The beginnings of the new furnace were not necessarily trouble free, however, as experienced in 1872 by Pilkington Brothers whose first tank failed suddenly after a promising one-week operation because worn-out bottom refractories caused the whole furnace to collapse. Design improvements first allowed a second tank to run nonstop

for 97 days and then led pot-furnaces to be abandoned at a rapid rate as 12 tanks were working in May 1877 and more were being built. At that time, tanks were 9 ft wide and 36 ft long. When new, they held 2 ft 6 in. of melted glass and then smaller amounts when the side refractories were wearing thin and thus becoming subject to bursting. As a matter of fact, the rapid wear of refractories required their renewal every 3–4 and 10–11 months for the sides and bottom of a furnace, respectively. In both cases, the operation took about three weeks. One more improvement was then brought when the depth of the tanks was increased (Figure 9) to form “a layer of chilled glass on the surface of the bottom, at which point the movement of the particles cease, whereby the bottom blocks will be protected from wear, the presence of stones in the glass avoided, and a larger proportion of high-quality glass will be produced” thanks to the fact that “the tank is maintained full of metal” [36].

3.6 Toward Continuous Processes

As summarized by M. Cable [37], “the regenerative tank furnace was the greatest advance in glass technology since Roman times.” The raw materials were fed at one end to be melted when progressing toward the other end where the *metal* was cooled down to reach the right viscosity for the shaping operations. Window glass manufacturing thus became close to be a nearly continuous process. The glass no longer needed to be melted for 24 hours in pots, which ensured the aforementioned time, fuel, and labor savings. Sheet and container glass-makers were among the first to adopt the new regenerative tank furnace in Britain and continental Europe, but less so in the United States, where the first was not built until 1889.

At the Compagnie de Saint-Gobain, however, the new technology was not regarded as capable of producing good-quality plate glass. The first tank furnaces were eventually built to produce rolled glass in the Saint-Gobain plant in 1881 and two in Stolberg, the first in 1884 and the second, an end-fired furnace, in 1888. Valuable data on the yield of these tank furnaces are found in a 1911 internal report where a plant manager recorded productions of 0.48, 0.4, and 0.36 tons per day and m² in Montluçon, Saint-Gobain, and Pisa (Italy), respectively, which are actually only a few times lower than achieved today in float-glass plants (Chapter 1.4).

The crown process had been abandoned since the end of the previous century. It could no longer compete with the cylinder process because of its smaller, circular sheets, less uniform thickness, and much higher waste upon cutting. But the increased throughput ensured by tank melting required more efficient methods for flattening the cylinders and annealing the flat glass obtained

Figure 10 Bievez lehr for the annealing of nine glass sheets [38]. Newly made sheet introduced in e; hearths in b and b'; sheets lying on iron frames moved to the next place from one to nine by a set of iron bars raised by a lever placed in Y.

[10]. In the new type of annealing *lehr* (*pattern*, in German) patented in 1866 by the Belgian worker Désiré Bievez [38], a much improved productivity resulted from movable tables carrying the sheets to be cooled, which entered at right angles from the flattening furnace (Figure 10). These were laid upon frames furnished with counterbalance-weights to facilitate their upward and downward motions given by a lever placed at the end of a connecting-bar. Moving all the sheets successively from first to last place was so easy that two annealing furnaces could be operated at the same time by a single worker. The new process ensured not only a reduction of the annealing time from 7 to 8 hours to 25–30 minutes, but also a better flatness and improved mechanical properties thanks to the same cooling rate applied on both sides of the sheets.

3.7 Rolled, Printed, and Wired Glass

Thanks to its perfect match with glass, the steel introduced in a highly visible way in the early nineteenth-century architecture enhanced the demand for large glass panes. As a consequence, processes were improved to make panes wider and at lower cost. In the rolled-glass process [39], the melt was ladled directly from the melting pot onto the casting table and rolled as done for plate glass. One, two, or more ladles could be used for one sheet, which could thus be made long and narrow and also thinner than usual plate glass at a cost much lower than with the cylinder process. Weight and cost advantages led this glass to be extensively used for greenhouses or roofs of railway stations. Well-known examples were in London the Crystal Palace (Figure 11) and the Paddington Great Western Railway Station (1858), in Paris the greenhouses of the Jardin des Plantes (1854) and the former Halles centrales (1855), or in Milan the Prato Centrale railway station (1862). The annual production thus rose to more than $0.56 \cdot 10^6$ m² in 1884 and reached $0.92 \cdot 10^6$ m² in 1898.

Figure 11 The original 563 × 139 m large and 39 m high Crystal Palace designed in two weeks by the famous gardener Joseph Paxton (1803–1865) and built on time and on low budget in Hyde Park in London for the 1851 Grand International Exhibition. Its shape and size were entirely scaled from the maximum 10 × 49 in. size of the flat-glass panes produced at that time by Chance Brothers under the direction of G. Bontemps; French workers had to be brought to help produce the total of 84 000 m² of glass that were displayed in just five months within a 4000-ton iron framework. After the six-month Exhibition, the Palace was dismantled and re-erected enlarged at the top of Sydenham Hill where it was destroyed by a blaze in 1936.

Compared with plate glass, these sheets were of a lesser quality but their lower prices made not only new applications but also new processes possible. A case in point was the machine successfully developed in 1884 by George and Edward Chance, whereby the molten glass was poured down an inclined plane to pass in between a pair of iron rollers [40]. In 1890, the process was improved with the addition of a second pair of rollers to impress a given pattern. Printed glass was born.

Following this invention, another machine was developed in Paris by Léon Appert (1837–1925) to make wired glass. His first wiring machine combined two rollers in between which glass was poured in two successive layers to embed the wire. Later on, the process was simplified: the wire was clamped above the table at the correct height and the glass cast and rolled in the usual way. The roller forced the fluid glass through the meshes of the wire, to unit again beneath it, thus giving the desired result in one simple operation (Figure 12). Interestingly, from 1879, Appert had also been a pioneer in the use of compressed air to blow glass faster, bigger, and with a much improved hygiene because workers used to share their blowing pipes [41].

Figure 12 The making of wired glass from glass cast on two converging tables.

4 Plate Glass

4.1 Mirrors: From World-Famous Venice to Newborn Saint-Gobain

It was only with the advent of the float process in the 1960s (Chapter 1.4) that the age-old distinction between sheet and plate glass was abolished when surface smoothing became superfluous for the latter. Traditionally, glass had been produced thicker for plate than for window glass to bear first grinding with sand and then polishing with *rouge* (red, iron oxide) in order to impart the desired lustrous finish to its surface. While window glass was becoming common in the seventeenth and the eighteenth centuries, plate glass remained a luxury product. Because of its thickness, any discoloration was clearly noticeable whereas defects within the glass itself or surface unevenness meant that the product would fetch much lower prices.

The emphasis, therefore, had always been put upon high quality, which was the problem already solved by the Venetian glassmakers through the preparation of the raw materials and the control of the melting conditions of their *cristallo* glassware (Chapter 10.7). Only the purest ingredients thus went into the manufacture of this glass, namely the best alkali salts and pure silica in the form of expensively ground quartz pebbles. The whole batch was then very carefully prepared and fritted before being introduced into the melting pots. The fame acquired by Venice through the *cristallo* of course motivated foreign competitors to imitate its production in the form of glass pieces *à la façon de Venise* (in the fashion of Venice), which could be hardly distinguishable from the genuine production. As complained around 1607 by a glass dealer in Antwerp, “one counterfeits Venetian glasses so well that glass makers themselves are able to discern the difference only with great difficulty” [26].

The fame of Venetian glass was due not only to the *cristallo*, but also to the quality of the mirrors sought after by the wealthy Europeans. Thanks to their fire polish, the best were the curved mirrors known as *œil de sorcière* (sorcerer’s eye), which were directly cut from blown ware but were necessarily small. The importance of the market for larger mirrors represented a real incentive to newcomers so that the French king Louis the 13th published in 1634 an edict allowing two supposedly successful makers “to establish in this city of Paris a manufacture making plate glass for mirrors with special prerogative for a few years” [29]. Despite the hiring of workers from Venice and Altare, however, no progress was actually made so that a *Manufacture Royale des Glaces* was created in 1665 by Colbert (1619–1683), the French minister of finance. Even though it was privately owned, the new

company benefited from impressive financial and honorific privileges such as the royal coat of arms affixed on its gate or the livery that the gatekeeper was allowed to wear. In 1672, Colbert could eventually tell Louis the 14th that “our mirrors are now more perfect than those of Venice” [29] as actually illustrated by those of the famous *Galerie des Glaces* in Versailles. These had been produced in 1685 from cylinders made at Tournlaville (near Cherbourg, in Normandy) and silvered in Paris, close to the market to prevent such a valuable product from being broken upon long-distance transportation.

But the cylinder method had serious disadvantages. Sizes could not be greater than about 1 m (in modern units) because cylinders blown longer would have become too thin to be ground. The solution was thus to improve the old Roman casting of glass onto a very flat table. The inventor of the process was probably an elusive Bernard Perrot from Orléans [42]. Better known is the fact that a group of businessmen were granted Letters Patent in 1688 that gave them a monopoly for the manufacture of the cast plate glass for the French market and, later, for export as well. The new *Société des Grandes Glaces* rapidly moved its factory to the village of Saint-Gobain in Northern France where wood was cheap and plentiful. After eventful early years during which bankruptcy was lurking, the company eventually met with success and threatened the existence of the *Manufacture Royale* because of the much larger size of its own glass plates. In the end, Louis the 14th decided in 1695 to merge the two companies into the *Manufacture des Glaces de France*, which would become much later the *Compagnie de Saint-Gobain*.

To produce plates as large as about 3×2 m, the two major improvements of the new process were a large iron table used for casting and a heavy iron roller driven by two workers to flatten the glass into a sheet once any visible defect had been hand-removed (Figure 13). Two iron slips along the edges of the table determined the thickness of the plate whereas two other cast-iron guides fixed its width and prevented the glass from flowing onto the side-slips. After glass casting and hardening, the table was moved toward special kilns (*carcaises*) where the plate was cooled down and annealed before being ground, smoothed, and finally polished. The first two of the last operations were similar in that they consisted in smoothing the surface of the glass with a sand abrasive applied with iron plates. Upon grinding, most of the excess glass was removed with coarse sand before the defects introduced along the way by the bigger grains were eliminated with a finer sand. The glass surface then had a dull, gray appearance so that a polished surface was obtained through rubbing with iron oxide (*rouge*) applied with a felt-covered tool.

Figure 13 The original Saint-Gobain casting process for plate glass: glass poured from the pot brought by the crane and spread with an iron roll before being transferred for annealing to a one of the horizontal *carcaises* on the left-hand side in the background [16].

4.2 A Craving for Plate Glass

In theory, the casting process was straightforward. In practice, however, it required not only much manpower but also a very large capital outlay as three million pounds were, for instance, spent between 1665 and 1702 by the French investors [42]. Instead of the small customary glasshouse, a wide hall was needed with a large melting furnace in the center, a casting table, a crane to transfer the pots from the furnace, a series of *carcaises* for annealing each plate made at a time, the machinery required for grinding and polishing [8], and also a storage warehouse. Such large investment cost makes it understandable that Saint-Gobain did not have many competitors for a long time, in England from only 1770 when former Saint-Gobain employees were hired at Ravenhead without having really been able to match the original quality [42]. The advantages of the new plates were such, however, that architects installed large mirrors in the halls, galleries, and reception rooms of the very affluent to play with light and shadow and create intriguing perspectives. Market demand thus increased smoothly but steadily through the eighteenth and nineteenth centuries when applications included not only large mirrors fixed above fireplaces and other elements of architectural decoration in

bourgeois apartments but also shop windows, making at the same time larger sizes desirable (Table 1).

Melting kept being made in pots containing about 2.5 tons of glass in regenerative gas furnaces, preceding casting and then annealing in *carcaises*. In 1893, $2.4 \cdot 10^6 \text{ m}^2$ of plate glass were manufactured in Europe at a cost of 15 francs per m^2 in France, which was down from 95 F in the 1820s thanks to cheaper soda (Chapter 10.11) and continuous increases of the size and efficiency of the furnaces [42]. In 1897, seven plate-glass factories were in operation in France, five in Belgium, six in Germany, six in England, one in Russia, one in Italy, and four in the United States. The surface produced in Europe had then increased to $3.6 \cdot 10^6 \text{ m}^2$. During this period, the US production increased from $0.5 \cdot 10^6 \text{ m}^2$ in six factories to $1.2 \cdot 10^6 \text{ m}^2$ in 13. In parallel, the time needed to make plate glass had been halved since 1765 thanks to the introduction of new mechanical means for casting, grinding, and polishing [29]. This importance of machines in glass-making was acknowledged by the high hierarchical levels reached in glass companies by mechanical engineers, as illustrated by Lucien Delloye (1856–1938) who ended up being the very influential head of the plate-glass division of Saint-Gobain [43].

Table 1 Maximum size and price of plate-glass sheets [33].

Date	Surface area (m ²)	Length (m)	Width (m)	Price for 1 m ² (1 × 1) in French francs
1806	4.25	2.50	1.70	226 (1805)
1839	8.73	3.80	2.30	127 (1835)
1844	11.66	4.30	2.70	
1855	18.40	5.40	3.40	61 (1856)
1867	21.80	5.90	3.70	47.75 (1862)
1878	26.50	6.40	4.10	40.30 (1884)

4.3 Toward Continuous Processes: Bicheroux and Boudin

The move from batch to continuous production of plate glass eventually began between 1910 and 1914 with the process designed by the Belgian engineer Max Bicheroux in Herzogenrath (Germany), a factory owned at 50% by Saint-Gobain from 1905. As somehow derived from the Chance process, the new one [44] consisted in casting the glass melted in pots between two iron rollers on a table whose tilt was increased as casting proceeded and the glass was cooling (Figure 14). But the period of the First World War was of course not the best to promote technical innovation in glassmaking. Whereas most plate-glass factories were still using late nineteenth-century methods in 1919 [29], Bicheroux’s innovation did spread in the 1920s in most plate-glass works not only at Saint-Gobain but also in other companies after a license had been sold to all European and American plate-glassmakers within the framework of the 1904 *Convention Internationale des Glaceries (Plate-Glass International Convention)* founded at the initiative of L. Delloye.

Another innovation was the tunnel furnace designed to anneal plates slowly moving in a temperature gradient from 650 to 550 °C in about half an hour. Thenceforth, casting tables of 10 × 5 m had no longer to be moved from the casting spot to the carcase but could be fixed and reinforced instead, which was much more favorable for product quality. At the same time, better use was made of mechanical power for the grinding and polishing process.

To get closer to a continuous process, the obvious next step was to substitute tanks for pots for glass melting. It was the development of alumina-based electro-cast refractories in 1925–1930 that made this substitution possible. After it had been noticed that some *stones* were so difficult to dissolve that they might yield better refractories if they could be melted, these materials were first synthesized from sillimanite (Al₂SiO₅) at Corning Glass Works in 1923 by H.P. Hood and G.S. Fulcher (1888–1871), of VFT viscosity-equation fame (cf. Chapter 10.11), for providing a better resistance to glass

Figure 14 Plate glass processes. (a) Sketch of the evolution. (b) Glass flowing from the melting pot in the Bicheroux process at the Herzogenrath plant in 1966. Source: Photo courtesy Saint-Gobain Archives.

corrosion. After melting with the electric-arc, these liquid oxides indeed crystallized as dense refractories with a low porosity that reacted much less with the molten glass than previously available materials. The new refractory

was made by Corning not only in the United States in 1927 for its expanding lighting glass-bulb business in a joint venture with Hartford Empire (Chapter 6.9), but also in France in 1929 and Japan the following year through other joint ventures with Saint-Gobain (which has become the current SEPR company) and Asahi Glass Co. [45]. Use of the new refractories for melting tanks was then rapidly implemented by Louis Boudin (1875–1967) in 1932 in the then most recent Saint-Gobain plate-glass factory of Chantereine, north of Paris. Even though the still hot glass tended to subside between the two rollers, the continuous sheet obtained was at least as good as that obtained by the Bicheroux process (Figure 15). By the way, this is the reason why the Boudin process is still used at present to manufacture printed glass.

4.4 Short-Lived Mechanical Feats: Continuous Grinding and Polishing

It still remained to grind and polish the plate glass on line to arrive at a fully continuous process. The initial impulse in that direction was given by a strong need for

Figure 15 The 3.2 m large continuous glass ribbon exiting the annealing lehr to be continuously ground and then polished with the Jusant machine, Chantereine plant, Saint-Gobain. Source: Photo courtesy Saint-Gobain Archives.

windshields when car production began to increase very strongly in the United States in the 1920s [24]. Without any experience in glassmaking, the Ford company was able to design a machine casting a ribbon large enough to make 40 in. windshields but it could not produce a glass of the required quality in a tank furnace. Through collaboration with Pilkington Brothers, the whole process was improved not only for melting but also for grinding of the glass pieces, cut right after annealing, in two distinct steps for the upper and lower side.

Additional developments were then made by Pilkington for the general production of plate glass in the form of a 60 in.-wide ribbon in 1924, and then of 100 in. in 1927, which could be ground continuously [24]. What was further needed was a machine that could grind and polish the glass ribbon on both sides as it emerged from the lehr before being cut into plates. Only the first operation was made with the twin-grinding process developed by Pilkington, however, which came into service in 1935. The twin grinder first ran at a speed of 1 m per minute, which was later increased by a factor of 5. It came to be used by all the main manufacturers in the world for the greater part of their plate glass production. But polishing was still made side by side on the sheets cut out of the glass ribbon whereas a glass fraction of about 30 % was lost in the grinding and polishing operations.

After having bought a Pilkington license for the twin grinder, Saint-Gobain went one step further with a complex polishing machine, the Jusant, whose prototype was installed in Pisa in 1956 to polish after grinding the glass ribbon emerging from the annealing lehr in a continuous way. Full production then began in November 1959, with a bigger machine installed at the Chantereine plant (Figure 16). The new process represented a mechanical feat, which was the culmination of an evolution that had begun three centuries earlier. But it was very costly in terms of both investment and operation, with 110 workers on the line, and kept wasting about 20% of the glass that was mixed with the abrasive products. Hence, it came too late and could not compete with the float process, which began production in the very same year (Chapter 1.4). The Jusant was thus discontinued after 10 years of use even though it was certainly producing the finest plate glass ever made at a rate of 15 000 m²/day.

5 Container Glass

5.1 The First Machines: Ashley and Boucher

By making continuous production possible, the Siemens tank furnace ensured a much greater output than the old pot furnaces as well as lower fabrication costs. For bottle production, working holes were opened in the melting tank just above the glass level in front of which fireclay

Polishing made with an aqueous suspension of Fe_2O_3 and FeSO_4 powders at an applied pressure of 50 kg/dm^2 exerted by nine machines, each made up to two pairs of two drums rotating at 600 rpm according to an eccentric circular motion in opposite directions above and below the glass ribbon. *Source:* Photo courtesy Saint-Gobain Archives.

rings were floating to allow a clean glass without scum or stones to be gathered for blowing made in the traditional manner. In 1886, Howard Ashley, of Castleford in England, reflected that much of the preliminary work to shape parisons (gobs) for mold-blown bottles might be performed mechanically. He introduced the parison or initial shaping mold, equivalent to the preliminary marvering and blowing of the glass. A further improvement by the same inventor was the use of compressed air for blowing up the bottle in the finishing or *blow* mold.

In France, the self-taught Claude Boucher (1842–1913) had been a pioneer when he built in 1878 a melting tank for the bottle-glass workshop he founded in Cognac. Later on, he designed in 1894 a manual compressed-air machine to replace the glassblower in all operations except gob gathering in the furnace [46]. The first mechanical bottles were made and sold in 1898. It then

appeared that its use allowed workers to be trained in a few months instead of 10 years and bottles to be produced 2.5 times faster (i.e. 120 per hour) and even 25 % faster than with the Ashley machine thanks to two alternating parison molds: while one was filled, the other could be used to shape the parison; as soon as the parison was blown and transferred to the finishing mold, the system was reversed to blow the glass already injected in the first mold (Figure 17). In 1906, 108 of his machines were working in many factories in France alone.

5.2 Finishing First

The late nineteenth-century pioneers had recognized that the finish of the container should be the first and not the last step [47], and that much of the work of a skilled blower's dexterous hand could be replaced with simple operations involving one mold to form the parison and another to blow the container itself. But their machines were still relying on a manual gathering step so that it remained to devise an automatic machine that would supply gobs of uniform weight and temperature. This problem thus slowed down complete automation of the process. It was not really solved until the early twentieth century, but then the new processes did not spread before the end of the First World War. So many qualified workers had disappeared that it is this labor shortage that induced glassmakers to use completely automated processes as the only possible way to supply the existing demand.

Physical properties such as density, thermal conductivity, viscosity, and surface tension and their respective relations to temperature all entered the problem [48]. Any changes in these parameters were at once noticed by a skilled worker who could address them through suitable and sometimes subtle adjustments of the duration of the gathering, marvering, and blowing operations or of the time of contact between the glass and the mold. Since a mechanical substitute could of course not compete in these respects, inventors had to find ways to ensure the constancy of the relevant parameters. They did it slowly and laboriously.

One of the first problems to be solved was that raised by the chemical composition of the glass. As late as in the early nineteenth century, these compositions were themselves problematic as they could devitrify readily because the emphasis was put on the low cost of the raw materials. English bottles of the late sixteenth and early seventeenth centuries could, for example, had less than 6 wt % Na_2O + K_2O but up to 40% CaO + MgO with liquidus temperatures higher than 1200°C , which could thus be managed in the furnaces of the period [49]. Even before the introduction of semiautomated machines, the ratio between alkaline earth and alkali oxides had already been reduced so that by 1904 they became compatible with modern

(b)

processes [50]. In the end, bottle glass progressively had become the soda-lime silica long used in tableware and flat-glass productions. Along with decreases of Al_2O_3 from 6 to 1% and of CaO from 20 to 7%, continuous increases of Na_2O from about 6 to 18 wt % and of SiO_2 from 60 to more than 70 % have, for instance, been well documented for English bottles throughout the nineteenth century [51].

5.3 The Feeding Problem

Not surprisingly, the first machines attempted at duplicating the gatherer's movements [48], but such *punty feeders* did not prove successful in this respect. Letting the glass flow by gravity from a hole in the glass tank was thus an obvious alternate option that was implemented in different ways in actual industrial production. The Homer Brooke feeder (Figure 18) is the best known of this type: a continuous stream of molten glass issued from the orifice fell onto a table supporting the parison molds. The device consisted of a series of cup-shaped cutting members and corresponding shear blades, which rotated in opposite directions about a central vertical shaft. A stream of glass flowed from the tank into one of a series of receptacles or molds, which rotated step by step about the central shaft. The opposite rotation of the cups and the shear blades caused them to meet and sever the stream before the cup was raised to support the stream while the mold was replaced by another. The cup then turned over and delivered its glass into the mold now

in place. But the device was actually so complicated to use that it had difficulties to compete with hand-gathering!

5.4 The Suction Feeder and the Owens Machine

At about the same time a completely different process relying on the principle of *suction* was successfully developed in the United States by Michael J. Owens (1859–1923). His machine [47] was operated next to an auxiliary furnace and included a revolving pot with a combustion chamber 3 m in diameter and 20 cm in depth, which was continuously supplied from the tank (Figure 19). A portion of the revolving pot projected somehow beyond the walls of the combustion chamber, exposing a segment of the glass surface. The gathering molds of the machine dipped into this exposed molten glass consecutively as the machine rotated; when dipped into the glass, a mold was automatically sucking it otherwise a vacuum would have been created within it, thereby forming the parison. As the mold rose up and moved away from the glass, a knife automatically cut off the string of glass that remained attached, dropping that portion back into the furnace. After the formation of the parison by partial blowing, the remaining steps of the process were similar to those of other types of forming machines, except that no inversion of the blank was necessary before the blowing step. The blank was simply transferred from its mold to the blowing mold suspended by the neck-ring mold.

In 1916, labor represented 53, 48, and 25% of the production cost of a bottle in handmade, semiautomatic, and Owens automatic processes, respectively [52]. Once the capital for the tank furnace, rotating pot and machines had been raised, the economic advantages of the Owens machines became obvious, but only after a while (Tables 2 and 3). Initially, it was not so much lower production costs that were advantageous, but rather the highly standardized and well-finished aspect of the bottles [53]. As one of the first automated machines, Owens' was quite successful in the United States but not in France where the investment problem raised, for example, by the high cost of molds was compounded by technical difficulties. In spite of furnace rotation, the quality of the glass was somewhat degraded by the periodic suction step. Even though automated machines could widely increase productivity, bottle makers generally preferred to keep their Boucher machines while waiting for the likely development of a successful gravity feeder.

In addition, the Owens machine did suffer from one technical defect that never got fixed [47], namely the formation of a "cut-off scar" at the bottom of the bottle where the tail that formed while the gathering mold lifted from the rotating pot was cut and chilled by the knife. As

Ware	Productivity increase	Labor cost decrease (%)
1 pint Whisky	742	90
5-gal carboy	994	83
1 quart milk	1449	95
0.5 pint soda	1149	95
4 oz. pharmaceutical	4110	97

long as bottles had thick bases, the problem was not very serious. When lightweight bottles appeared and spread, however, it became an important disadvantage as did the limitations on the design of parison molds resulting from the need to gather the right amount of glass by the mold.

5.5 The “Gob” Feeder, the Hartford-Fairmont Gravity Feeder (1915)

Progress toward the final solution was much slower in the evolution of the devices now called “feeder” in modern factories. The primitive “flowing stream” of molten glass needed to be controlled to render it intermittent and to separate it into lumps of charges suitable for entering the blank or parison mold of the forming machine. Numerous attempts were thus made to avoid the possible defects created by a stream of glass flowing into a mold or receptacle. These defects were resulting from the coiling, folding, or lapping upon itself of the flowing glass that were leaving disfiguring marks on containers. Because the surfaces of the coils or folds were chilled by contact with the relatively cooler atmosphere and cooler metal of the mold, the defects usually were taking the form of air bubbles or blisters and vein-like creases or depressions.

Efforts were thus made to handle the glass under more viscous or pasty conditions as done with hand-gathering methods. Instead of letting a fluid melt flow by gravity from the tank, the idea prevailed that it was better to impel, drive, or force a viscous liquid from an extension of the tank from which it could not otherwise flow or escape spontaneously too readily. This new *propulsion principle* was implemented in the Hartford-Fairmont feeder (Figure 20). A fire-clay “paddle” was employed for propelling or ejecting glass in timed surges or waves over a fireclay lip or dam such that the ejected glass formed a compact and cohesive charge, the gob, by a reciprocating needle or plunger situated over the hole delivering the gob to the machine.

A peculiarity of this feeder was to deliver glass at the working temperature, which was reached at the end of a long chamber where it cooled down after exiting the furnace. It was first designed in 1915 by Karl E. Peiler of the aforementioned Hartford Fairmont Company (which became Hartford Empire and is today Emhart) [21, 33, 48]: the feeder (forehearth) ended up in a lip beyond which the extrusion orifice was placed (Figure 20). Dipping into the chamber was a paddle that drove waves of glass of uniform size over the lip by a regular vertical and horizontal back and forth motion. The successive waves were forced through the orifice by a plunger (or needle) moving vertically. Being at the working temperature, the glass formed gobs whose size and

Figure 20 Hartford-Fairmont forehearth.

shape were determined by the length of the paddle stroke and its depth of immersion, the shape of the plunger, and the timing of the various motions.

This feeder might be used to supply either a single forming machine or three or four machines that were served by a hinged receiving trough below the orifice. This trough moved in turn in a *register* with water-sprayed, inclined, cast-iron troughs leading to the machines. The hot gob created a water-vapor cushion on which it rested as it slid down the trough, so tending to prevent deformation [54]. A major improvement in the Hartford-Fairmont feeder (1922) was the disappearance of the paddle that was replaced with a cavity created by a rotating refractory cylinder (tube) set over the orifice [21]: when the plunger rose in the tube, glass was drawn in the tube above the hole; when the plunger went down, a definite quantity of glass was expelled through the hole forming the gob (Figure 20). Hence, the Hartford-Fairmont feeder turned out to have solved the gathering problem that had until then blocked the way to fully automated machines.

5.6 Processing Machines Using a “Gob” Feeder

Referring to Chapter 1.4 for a description of modern container making, it will suffice here to note that the press and blow machines [32] were the first and the easiest machines to operate: the molten glass was gathered and dropped into the parison mold on which the neck-ring

mold was placed. The plunger then entered the molten glass to shape it in the former mold up into the latter where it was chilled. The plunger was removed and the neck-ring mold plus the parison (blank) lifted and transferred in one of the finishing molds. The blowing head was put into position and the bottle was blown to shape, removed, and annealed. But narrow-neck bottles could not be made by this method.

The general solution was to invert the parison mold, the neck-ring mold, and the plunger being placed at the bottom. Glass was dropped in at the top as before, the requisite quantity being cut off with the shears, plugged to shape the neck-ring, given a preliminary blow to form the parison (blank), and then transferred to the blow mold. Multiple molds rotating devices were developed to increase the production. A further improvement in bottle machines of the multiple-mold type was a device for the transfer of the blank to the blow mold, and an apparatus for removing the finished bottle from the blow mold. A number of such devices were invented. The O'Neill, Lynch, and Hartford-Empire machines are some of the best known.

6 Perspectives

As a backdrop to this whole story is a slow evolution of the refractories throughout the ages [55]. With wood-fired furnaces, temperatures did not exceed about 1100 °C so that pots made with sandstone and siliceous clays were adequate. The higher temperatures reached with coal then required more careful selections of clays. But it was only with Bontemps that the need for high purity and high-alumina contents was recognized along with the use of three parts of previously fired clay known as *grog* for one part of fresh clay to limit water contents and ensure much greater strength through better dimensional stability upon firing [19]. This progress and the switch from manual to mechanical pressing of bricks and the adoption of tunnel kilns for continuous firing in the early twentieth century paralleled the evolution of glassmaking and had obviously positive consequences for furnaces of any kinds before the invention of electrofused refractories.

In all branches of industry, the nineteenth century was a *Machine Age* dominated by practical applications of physics and chemistry. Glassmaking was thus no exception, as announced by the *Essay* on this *art* where Pierre Loysel (1751–1813) reviewed in 1799 topics ranging from raw materials and melting reactions to the size of furnaces and the shape of their vaults in relation to a square-law decrease of the heat intensity with the distance from its source [56]. Hence, the emphasis put here on a few

inventors such as the Siemens brothers should not conceal the fact that, in contrast with previous periods, innumerable engineers were at work and secured so many patents for their innovations that the century might alternatively be termed the *Patent Age*. A case in point is the furnace designed in the 1860s in Hannover by Henning Boetius for the manufacture of glass, iron, steel, and other materials. Its main feature was “to keep the bed of the furnace and the side walls of the fire-place cool, and to preserve the same from the destructive action of the heat for as long a period of time as possible” [57]. Thanks to its simplicity, low operating costs and simple control of the fire intensity through valves admitting more or less air, this kind of furnace would be widely used for contained glass until the mid-twentieth century (Figure 21).

In all branches of glass manufacturing, such efforts resulted in the development of mechanization at the turn of the nineteenth and twelfth centuries. Industrial developments were not as fast as they could have been, however. They meant not only a drastic change in factory organization, which did not suit well specialized glassworkers, but also required rather heavy investments at the beginning of the twentieth century when the European glass industry was meeting with difficulties on the American market. Heavy tariffs imposed by the American government on glass imports caused the traditional export market of European companies to collapse within a few years. The crisis lasted until the market was organized via at least two International Conventions for special and plate glasses, which considerably improved the situation.

In 1918, at the end of the war, the need for glass was huge and factories had to resume production as fast as possible. Thousands of glassworkers had disappeared and numerous continental factories had been destroyed. They were rebuilt with integration of mechanical processes that had mostly been designed before the war. As clearly spelled out by the Siemens brothers, the main thrust behind glassmaking improvements had been the achievement of cost reduction, which mainly resulted from the efforts made to improve the energy efficiency of the processes and from the switch from batch to continuous operations. The resulting decrease in the numbers of qualified workers was a constant source of conflict, especially with blowers who had always considered themselves as a kind of labor aristocracy [58]. Of course, these efforts were not interrupted once mechanization became fully achieved in the early twentieth century but were renewed in the last part of the century as a result of rapidly increasing energy costs. To summarize the results achieved, it will suffice to state that the amount of coal burnt was 2.5 times that of glass produced before the regenerative furnace was invented, and now would be 25 times smaller. The continuous nature of the process

Figure 21 A Boetius furnace for the melting of crystal glass in 12 pots [20]. Coal brought by two lateral openings transforming into coke upon reaching the grids D on which it is gasified before mixing with the preheated air (circulating through the canals F of the regenerator and H of the siege supporting the pots) and burning up to the crown.

largely contributed to this dramatic reduction through quicker operations, faster melting, and, thus, lower fuel consumption.

At the same time, working conditions markedly improved by making close contact of workers with the furnaces and molten material unnecessary. One of the main reasons why Boucher invented his machine was his concern for the health of workers who were suffering from eye, throat, and lung diseases under difficult conditions of the workshop where sharing of blow pipes by workers was the rule. Ironically, his invention initially caused social unrest among glassblowers who were fearing to lose their jobs. In the end, however, the improvement he brought them earned him in 1902 a price of the French Academy of Sciences. The situation was not peculiar to France [59]. But speedier and more economical means of production led to a greater demand for the output so that wages increased instead of decreasing as exemplified in Saint-Gobain where the average yearly wage increased from 530 to 1530 francs from 1830 to 1910 [42]. This obstacle removed, progress toward a higher state of development of machinery in glass factories was much more rapid. The numbers of blowers did decrease markedly, however, from over 6000 in the United States in 1896 to about only 1000 in 1924 for a production that tripled during the same period [53].

Another important feature was the dynamical nature of both production and markets as currently illustrated by the development of glassmaking in Asia (Chapter 9.6).

Particularly noteworthy in this respect was the very rapid development of flat glassmaking around the city of Charleroi in Belgium throughout the nineteenth century [60], which was fostered by the local availability of coal and good sand, a central geographical location, and innovative engineers exemplified by D. Bievez or É. Fourcault who designed at the beginnings of the twentieth century the first process from drawing directly flat glass (Chapter 1.4). With a production that was exported all over the world, however, this industry was highly sensitive to increases of its labor and coal costs and to abrupt changes in tariffs imposed, for instance, by the United States, an important market.

To conclude this short review, it is appropriate to note that the three centuries of efforts that resulted in the continuous production of plate glass were almost instantly ruined by the invention of the float process, which has become a textbook example of *disruptive* innovation. There is in fact some analogy with the old-age oil lamp, which took more than two millennia to become fully optimized just a century before being made obsolete by the electrical lamp (Chapter 6.9). Glass remained a fundamental component of the lighting device, however, actually the only one common to both of them.

N.B. A passage of the *Annals* of the Byzantine chronicler Niketas Choniates (~1155 to ~1216) has come to our attention after the present chapter was written. Glass historians might be interested in knowing that, when his astrologers predicted apocalyptic winds, the emperor

Manuel Komnenos (r. 1143–1180) “sought caves and hollows as protection against the winds and prepared them for habitation; he removed the glass from the imperial buildings so that they should not be damaged by the blasts of the winds while his attendants, kinsmen and sycophants also anxiously involved themselves in these undertakings, with some burrowing into the earth like ants and other making tents, fastening them with threefold cords and cutting sharp pegs to serve as supports” [61]. The story is similar to the Duke of Northumberland’s [3], but has the great interest of antedating it by four centuries.

Glass, the Wonder Maker of Science

Pascal Richet

Institut de physique du globe de Paris, Paris, France

1 Introduction

Glass was first the preserve of elites of the Late Bronze Age (Chapter 10.2). Its variety of vivid colors was clearly distinguishing it from other man-made materials and even allowed glassmakers to imitate highly prized gemstones [1]. Its chemical inertness, tightness to air, and limitless shapability were then put to good use in many kinds of vessels when blowing of transparent glass became common toward the beginning of our era (Chapters 10.3, 10.5). Along with optical isotropy, these properties made glass the science material *par excellence*. Without any overstatement, one can even claim that science as we know it would not have existed without glass. Of course, other kinds of materials have participated in the scientific enterprise but none of them, to begin with metals such as copper and mercury, have played a comparable key role.

The claim is obvious for optics whose laws required not only transparent, but also isotropic solid materials to be established. “It is with the prism that Newton anatomized light, and stole this knowledge to the celestial intelligences that alone had it before him,” gracefully acknowledged the famous *Encyclopédie* [2] of Diderot and D’Alembert in the eighteenth century. As also stressed by the *Encyclopédie*, it was in addition certain that, “ever since the discovery of metals, Chemistry did not make a more marvelous and useful discovery than that of glass.” It is actually well known that, as early as in Antiquity, the two fields of optics and alchemy were the first ones that emerged thanks to glass. At least to some extent, however, it would be difficult to find a single branch of science that did not rely on glass.

This statement remains true even if one discards its ancillary uses in spectacles, lamps, or clocks and

especially in microscopy slides or photography plates, without which much work could not have been done, or neglect the bubble level invented in 1661 (description in 1666) by the polymath and diplomat Melchisédech Thévenot (1620–1692) [3], which was soon after appended to many kinds of precision instruments. Actually, it is not commonly acknowledged that in two different ways the use of glass was a major driving force behind the Scientific Revolution of the seventeenth century. First, it was glass lenses that induced a complete change in man’s worldview by having made the exploration of infinitely large and small possible with the telescope and the microscope, respectively. Second, although emphasis regarding the Scientific Revolution is usually put on mechanics and on its mathematization, one should not overlook that glass also gave physics and chemistry a sounder quantitative basis through the definitions and measurements of the fundamental variables of temperature, pressure, and different electric charges, the study of air pressure having in particular settled for good the fundamental question of the existence of vacuum.

Of course, glass thermometers and barometers have now been replaced with electronic devices, but the advances made in glass science and technology illustrated by a great many chapters of the Encyclopedia have never ceased to be exploited in scientific endeavors. A striking example is that of pH meters, which, after chemical optimization of their glass electrodes, have become from the late 1930s the chemical instrument most widely employed in academic, industrial, and natural contexts (Chapter 5.8).

Without any claim to comprehensiveness, this chapter thus aims at illustrating the fundamental importance of glass for science. Optics will first be dealt with, followed by alchemy and chemistry. Through temperature and pressure, two of its intensive variables, physical chemistry will then be considered. Finally, a brief review of electrical

Reviewers: R. Kerner, Physique théorique de la matière condensée, Sorbonne Cité, Paris, FranceG. Strano, Museo Galileo, Firenze, Italy

research will illustrate how, from the discoveries of mercurial light and two kinds of electric charges in the early seventeenth century, glass led to the birth of subatomic physics at the beginning of the twentieth.

In preamble, it is useful to recall that the term *science* is anachronistic to describe activities in the past. Being a derivative of *scio* (I know), the Latin term *scientia* was designating a rational knowledge based on firm foundations. As an early translation of the Greek term *philosophia* (*love of wisdom*), it gave rise to the expressions of *philosophical*, *moral*, or *religious* sciences. The Latin term closest in meaning to the modern *science* was *disciplina* (action of learning) whereas the term *art* (*ars*) also took on a broad meaning to designate, as the Greek *tekhnè*, any trade or human know-how practiced by *artists*. From Isaac Newton (1643–1727) to William Thomson, better known as Lord Kelvin of Largs (1824–1907), savants thus traditionally considered themselves as *natural philosophers* and their practice as *natural philosophy*. In the English-speaking world, they became very lately *scientists*, after this term was coined by the Anglican priest and polymath William Whewell (1794–1866) (e.g. [4]).

2 The Source of Optics

2.1 The Study of Refraction

The earliest optical observations likely involved the still surfaces of ponds onto which the landscape was reflecting and through which partially immersed straight poles or oars showed a marked kink at the interface with the air. Dating back to the mid-eighth century BCE in Mesopotamia for the earliest, intriguing lens-shaped pieces of rock crystal (quartz) or glass have been found in the archeological record [5, 6] but their use as magnifying glasses seems unlikely, in agreement with the fact that it is not documented in the ancient literature [6]. Better known were reflection and refraction effects, such as a fire kindled by a beam of light passing through a glass filled with water, which could have been commonly observed with the vessels and vases present in every household when transparent glass became a commodity in the Roman Empire (Chapter 10.3). The Latin philosopher Seneca (4 BCE–65 CE) thus reported that “writing, however tiny and difficult, is seen larger and clearer through a glass full of water” and even that “the stars themselves seem larger if one looks at them through a cloud” [7]. In agreement with the ideas of the period, however, Seneca added that the “eyesight falters in moisture and cannot reliably grasp what it wants to” especially because images were distorted at the same time they were enlarged.

The concepts of *ray of light* and *reflection* had been formulated early through the study of mirrors, in particular, which were made up of metals. Glass thus entered the scene only with the experimental study of refraction performed by Claudius Ptolemy (second century) in Alexandria [8], the stronghold of Greek science, which happened to be close to the main areas of production of Roman glass (Chapter 10.3). Like his Greek predecessors, Ptolemy did not try to understand light itself in geometrical terms, but what the eye was seeing. His interest in refraction was thus closely related to his astronomical work [9], for which he is best known since the geocentric system of the world expounded in his *Almagest* would remain basically uncontested for nearly 15 centuries.

With a graduated brass disk similar to that used for his astronomical observations, Ptolemy measured angles of refraction at three interfaces, namely, air–water, air–glass, and water–glass (Figure 1). He then reported in his *Optics* that refraction occurs “not only in the passage from rarer and more tenuous to denser media — as happens in the case of reflection — but also in the passage from a denser to a rarer medium” in such a way that the angles of incidence and refraction “do bear a certain consistent qualitative relation to one another with respect to the normals.” Possibly because he did not observe a constant ratio between the angles of incidence and refraction (Figure 2), Ptolemy contented himself with stating that this ratio increases with these angles. Deviations of his data from the theoretical values (Figure 2) make it in fact likely that he corrected his observations by 0.5° at small angles and by 2° near 80° such that, in modern notation, the differences between two successive measurements were following relationships of the form $\theta_r = a\theta_i - b\theta_i^2$ between the angles of refraction (θ_r) and of incidence (θ_i) [10]. Would it be indicative of an influence of Babylonian mathematics, which relied heavily on such arithmetical progressions? Whether or not this was the case, Ptolemy’s measurements look surprisingly modern, contradicting the common opinion that experimental work was ignored in Antiquity. But their results did not translate into any application. On the one hand, the effects of refraction were rather thought to be problematic whereas, on the other, Ptolemy and his fellow astronomers were primarily interested in the noble and divine harmony of celestial movements.

Ptolemy’s *Optics* is actually known through a twelfth-century Latin translation of the Arabic version, which was then lost like the Greek original. It was in Islam that further progress was made in optics, especially by Ibn al-Haytham (965–1040), better known as Alhacen in the Latin West. In his own *Optics* [11], this astronomer and mathematician was also interested in vision but his main

Figure 1 The concept of ray of light at the basis of Ptolemy's study of refraction between air, water, and glass: angles of incidence of rays measured with a graduated bronze disk as a function of angles of refraction set by a marker placed at the center of the disk and a peg repeatedly moved by 10° . Set up reconstituted in [9].

Figure 2 Anachronistic geometrical representation of Ptolemy's refraction measurements between air, water, and glass [8]. Data calculated from Snell–Descartes law included for comparison (curves) with refractive indices of 1.33 and 1.52 for water and glass, respectively.

innovation was to consider light as an independent physical entity that had to be investigated geometrically for its own sake. In Book VII of his treatise, the principle of the magnifying lens was in particular clearly described: “if an object is placed in a dense spherical medium of which the curved surface is turned towards the eye and is between the eye and the centre of the sphere the object will appear magnified” [11]. But glass did not become the basis of any optical devices. Al-Haytham's *Optics* itself was even largely overlooked since a single ancient manuscript has transmitted its entire original Arabic text.

2.2 The Marvels of Refraction

It was through its Latin translation probably made at the turn of the twelfth and thirteenth centuries that al-Haytham's *Optics* did find interested readers, among them the visionary Franciscan friar Roger Bacon (~1217–1292). By then it had been understood that changes in images are determined by the shape of the glass pieces through which an object was seen, and not by some intrinsic virtue of the material. Optical applications had, therefore, become possible. In his own *Optics* illustrated with many diagrams, which he included in his *Opus maius* (*Great Work*), Bacon thus wrote that “We can so shape transparent bodies, and arrange them in such a way with respect to our sight and objects of vision, that the rays will be refracted and bent in any direction we desire, and under any angle we wish we shall see the object near or at a distance” [12]. In other words, Bacon understood that refraction was the key phenomenon that would make any kind of visual effect possible as angles, and not distances, were the basic parameters to be dealt with. Because of refraction, convex lenses, for example, cause a parallel beam of light to converge at a point, the focus, which is closer the stronger the curvature (Chapter 6.1). Conversely, concave lenses make it to diverge. By combining these two types of lenses, it was possible to make the light follow any desired path. As stated by Bacon,

Thus from an incredible distance we might read the smallest letters and number grains of dust and sand owing to the magnitude of the angle under which we viewed them, and very large bodies close to us we might scarcely see because of the smallness of the angle under which we saw them,

for distance in such vision is not a factor except by accident, but the size of the angle is. In this way a child might appear a giant, and a man a mountain.

Although it took a few centuries to design the telescope and microscope anticipated by Bacon in his book, which was widely read, it is probably no coincidence that the first spectacles were invented at his own time, in Tuscany, to correct far-sightedness with convergent lenses [13] whose optical quality did not need to be very high. Thanks to the isotropy of its optical properties and relative ease of production, glass rapidly proved to be more appropriate for optics than crystals such as quartz and beryl, which were also used early (beryl having yielded the German word *brille* for spectacles), whereas a new mode of machining also helped, which consisted in polishing the lenses with spherical tools of the curvature that was desired.

Shortly afterward glass was involved in other noteworthy experiments made by the Dominican friar Dietrich of Freiberg (~1250–after 1310) to understand the nature of the still elusive rainbow [14]. Using glasses filled with water to simulate the propagation of light within a single droplet arrested in its fall, Dietrich masked various parts of the vases illuminated by the sun to find out that light undergoes a first refraction when entering a droplet, then a reflection when reaching its rear, and finally a second refraction when leaving it in the direction of the observer (Figure 3). By raising and lowering slightly the vases, Dietrich also noticed changes in the color of the ray and concluded that each color seen by the observer is coming from a number of neighboring droplets. Finally, the secondary rainbow sometimes seen above the primary could be explained in terms of a double reflection of rays entering a droplet near its top, which made these rays leaving it

Figure 3 The rainbow as understood by Dietrich de Freiberg: parallel light of the sun entering water droplets from the left and leaving it toward the observer's eye after a first refraction, a reflection and a second refraction. Part of an original sketch [14].

upward in the reverse order of colors as compared with the primary rainbow, and with a much reduced intensity due to the relative scarcity of such double reflections. Interestingly, similar experiments were made at the same time in Iran by the mathematician al-Fârisî (1267–1319), who arrived at similar conclusions in his *Revision of Optics*.

2.3 The Exploration of the Universe

Because they were more difficult to shape, divergent lenses were not developed until the sixteenth century to relieve myopia when, resulting itself from a markedly growing need of books, the invention of the printing press had in turn enhanced further book reading. It is probably not fortuitous that the telescope was invented when these lenses became common. Chance likely played some role in its invention. According to tradition, the first step was made in the Netherlands in 1608 when a lens maker, Hans Lippershey (1570–1619), asked for the exclusive right to sell an instrument with which distant objects appeared larger and distinct. When two spectacle makers contested Lippershey's request, the rumor of such an interesting invention had in fact already spread so quickly that the instrument itself had reached Rome and was sold in some Parisian spectacle shops in the spring of 1609. Actually, the story cannot be told that simply. The fact that Middelburg, Lippershey's hometown, was at that time a thriving glassmaking center, which was producing the highest-quality products of the Dutch Republic was unlikely coincidental [15]. But the invention of the telescope cannot be assigned to any single person: rather, it represented the outcome of long evolution in which progress made in lens grinding in the early sixteenth century played in particular a considerable role [15].

This complexity notwithstanding, Galileo Galilei (1564–1642) heard of the instrument while being in Venice in July 1609. He hastened to make his own by grinding and polishing two kinds of lenses, concave for the ocular and convex for the objective, and placed them at both ends of a wooden tube about 1 m long (Figure 4). As a reward for the military value of his *occhiale* (spectacles, in Italian) or *perspicillum* (from the latin *perspicio*, to see clearly), the *Serenissima Repubblica* offered Galileo a highly paid faculty position, which he eventually declined. Quickly, however, the idea came to him to use the *spy-glass* for something completely different than checking the enemy sails: to peer carefully into the heavens.

Although observations were made difficult by a narrow field of view and the need to keep the eye stuck to the eyepiece, countless unknown stars were seen, four satellites of Jupiter discovered and the rugged surface of the Moon ascertained and depicted. Following by 67 years the *Revolutions of the Heavenly Spheres* of Nicolaus Copernicus

Figure 4 The objective of Galileo's telescope. These instruments had a typical magnification of 20, as given by the ratio between the focal lengths of objective and ocular lenses, a field of view of about 15 arc min and a resolution of 20 arc s [16]. Apertures of the ~45 mm convex and ~20 mm concave lenses reduced with cardboard rings by up to 50% to minimize optical aberrations. Source: Photo Franca Principe, Museo Galileo, Florence, inv. 20121.

(1473–1543), Galileo's *Messenger of the Stars* [17] quickly published in March 1610 unveiled these epoch-making discoveries and gained its author a high European reputation. In further observations, Galileo detected the strange appearance of Saturn, spots at the Sun's surface, and the phases of Venus. But the main outcome of his work was that two small glass lenses had shaken into pieces the ancient Aristotelian cosmos, finite, immutable, and hierarchically ordered, bounded by the perfect sphere of fixed stars and centered on the most humble Earth [18]. As stated by Copernicus, the Earth was instead one of the planets orbiting the Sun, and Galileo also concluded that the fundamental distinction between the corruptible terrestrial matter and the immutable *quintessence* of the heavens had to be forgotten.

2.4 Practice vs. Theory: Some Real Problems

To improve income and satisfy the curiosity of Princes and wealthy amateurs, Galileo polished countless lenses and sold dozens of telescopes (but avoiding to do so with potential competitors!). A great many seventeenth-century scientists did the same, but all shared the difficulty of finding good glass. With an index of refraction of about 1.52 and a low dispersion (Abbe number of about 60, cf. Chapter 6.1), the *crown* glass used in optics was plain window glass, deriving its name from the eponym process (Chapter 10.8). But it was suffering from a great many defects, namely, streaks, striae, veins, or tails caused by inadequate annealing, chemical heterogeneities, or contamination of the melt by the pots, by the marble plates on which gobs were rolled or by dirt, which

would have been very difficult to eliminate even with the much higher melting temperatures reached in modern furnaces (Chapter 1.2). Hence, the physicist Nicolaas Hartsoecker (1656–1725) still deplored in 1694 in his *Traité de dioptrique* [19] that “out of more than two hundred large glass plates that I polished with great care, I could only find two reasonably good and five fair” to be used for his own microscopic observations, of animal semen in particular.

Following briefly Galileo's work, the law of refraction had been formulated (without demonstration) by the mathematician and astronomer Willebrord Snell (1580–1626) in the early 1620s. As indirectly known [20], it stated that

If the eye O (in the air) receives a light ray coming from a point R in a medium (for example, water) and refracted at S on the surface A of the medium, then O observes the point R as if it were at L on the line $RM \propto$ surface A . Then $SL:SR$ is constant for all rays.

In mathematical terms, the law states that $\sin r: \sin i$ is constant, where i and r are the angles made by OS and SR with the normal to A at S . As demonstrated by René Descartes (1596–1650) in his *Dioptrique* in 1637 [21], the ratio between the sines of the angles of incidence and refraction of light between two media is indeed constant. This constant was lately defined as the *refractive index* by the polymath Thomas Young (1773–1829) to characterize the relative ability of a medium to deflect light. Without this definition, however, Snell-Descartes law had already made in principle possible to calculate the shape to be given to lenses to improve instruments and obtain the desired effects. No matter how carefully lenses were prepared, however, images were increasingly blurred when the magnification was increased. This effect would be termed *chromatic aberration* when later understood (Chapter 6.1).

This aberration problem was the main one to be faced in the design of telescopes and microscopes. Although Galileo himself saw flies looking as big as lambs with his instrument, an inverted telescope is not a microscope: its field of view is much too narrow because the divergent light coming from an object at very close distance cannot be focused like the parallel light emitted by a distant star. Built in the Netherlands on a scheme established by the astronomer Johannes Kepler (1571–1630), the first *compound* microscopes closely followed the telescope. They had two convex lenses whose distance was varied to change the magnification. But it required a few decades for the observation of small things to lead to great discoveries. Although glass corrects vision, it distorts it still more easily. Even at moderate magnifications where

chromatic aberration is not yet detrimental, observations are especially tricky when the object has to be illuminated, the focus delicately achieved and small lenses prepared to produce sharp images. In addition, Nature had to be examined directly assured the old scholastic tradition whose vestiges maintained a certain distrust toward the microscope.

2.5 An Astonishing Microscopic World

One of the first to overcome a good part of these difficulties was the physicist Robert Hooke (1635–1703) with the 30–40 magnification of his microscope described in 1665 in *Micrographia* [22]. His instrument comprised two lenses placed in a 20-cm long cardboard tube whose distance was varied with a thread engraved in a wooden support, while the light of an oil lamp was focused on the observed specimen by a spherical glass bulb filled with water (Figure 5). His experiments were made with various kinds of lenses and with “waters, gums, resins, salts, arsenic or oils.” As Hooke concluded in his preface, however, none are “more useful than that which is made with two glasses.”

But the true appearance of the specimen observed was difficult to ascertain because “the aperture of the object glasses are so small that very few rays are admitted and [...] the object appears dark and indistinct.” As a result, emphasized Hooke, who was first trained as a painter, “I never began to make any draught before, by many examinations in several lights and in several positions to these lights, I had discover’d the true form.” A mix of pure science and popularization, *Micrographia* also created sensation with its great many careful drawings, which, for instance, revealed the highly complex nature of fleas and flies, and with Hooke’s perspicacious comments. These led him in particular to coin the word *cell* for describing the small lodges observed in thin slices of wood, and to interpret the geometrical shape of crystals in terms of the arrangement of minute particles (Figure 5).

Like telescopes, microscopes diversified quickly [23] but magnifications higher than about 40 could not be achieved with the various kinds of compound instruments designed. It was with a miniature version of the magnifying glass that a magnification of up to 270 and a resolution close to 1 μm were reached by the self-taught Antoni van Leeuwenhoek (1632–1723). Apprentice in his youth to a cloth merchant before becoming a bailiff and surveyor in Delft, Leeuwenhoek took his inspiration from the instrument used by drapers to inspect fabrics. In a way that is still elusive, his convex lens was carefully ground and polished from a glass globule a few millimeters in diameter. It was clamped between two perforated metal plates 5 cm long and 2.5 cm wide to which was attached

the sample holder, which could be rotated in the three directions of space. The sample could thus be brought conveniently and stably into focus, which had to be done next to the eye because of the very short focal length of the lens.

When he died, Leeuwenhoek left 247 microscopes mounted and 172 replacement lenses. As early as 1674, he understood that many of the microscopic things he was the first to observe were animals because they were moving freely. Spontaneous generation did not exist, he then demonstrated by describing bacteria and protozoa as well as spermatozoa of species ranging from mollusks to mammals (Figure 6). Dealing also with observations of nerves, muscular fibers, hair, elephant skin, snail eggs, bee legs, plant seeds, gunpowder, or salts of wine and vinegar, about 100 letters were written from 1676 to 1723 to be “Englished” for publication in the *Philosophical Transactions of the Royal Society* [25], which had been founded in 1665. Relative to a scale of size whose units were a sand grain, a beard hair, or a red globule, it was a whole new world replete with minute strange features and tiny living beings that Leeuwenhoek’s lenses revealed to the learned world.

2.6 The Anatomy of Light

In the form of “a small rod, grooved, or angular,” as also noted by Seneca [7], glass had the intriguing peculiarity of emitting “the kind of color seen in a rainbow.” In his room in Cambridge, Newton was struck in 1666 by the elongated shape of the rainbow produced by such a glass prism. A quick check showed him that this feature did not result from some defect of the prisms, which were “free from veins” and had their sides “accurately plane and well polished without those numberless waves or curls which usually arise from sandholes in polishing with putty” [26]. And light does not propagate along a curved path, noted Newton in his first paper on the subject [27], as done by “a tennis ball, struck with an oblique racket.” A series of experiments eventually led him to an *Experimentum Crucis*: after refraction by a first prism, red and orange rays were, for instance, refracted in the same way by a second prism with refrangibilities increasing again from red to violet. It followed that “whiteness is the usual colour of light, for light is a confused aggregate of Rays imbued with all sorts of Colors, as they are promiscuously darted from the various parts of luminous bodies [...] but if any one predominate, the light must incline to this color.” Newton then explained that images are blurred at large magnification because the focal length depends on light color, increasing from violet to red. It was the cause of the *chromatic aberration* of lenses, which he thought could not be corrected [26].

Figure 6 The *Animalcula* discovered in the *Semine masculino* of a cock, each having a “long and exceedingly small tail” not readily observed under the microscope by Leeuwenhoek who marveled at “an infinite number of those *Animalcula*, swimming in legions together, and crossing one another like clouds in a stormy day, and as brisk and lively as if the cock had been newly killed” [24].

2.7 Flint Glass: The Advantages of a New Composition

Glass eventually brought a solution to chromatic aberration. The starting point was the lead-bearing compositions that began to be made in England when a royal *Proclamation* forbade in 1615 the use of wood in melting furnaces (Chapter 10.9). Because of less efficient heating by the smaller flames of coal, some minimum (Pb_3O_4) was added to the batch to lower melting temperatures in pots that had to be covered to prevent reaction of the fumes produced with the melt. Because of lack of sand with low-enough Fe contents in England, high-purity flint became the silica source used and gave its name to the new glass. In 1674, the investor and dealer of Venetian glass George Ravenscroft (1632–1683) secured a patent for the *Manufacture of crystalline glass resembling rock-crystal* [28, 29]. He did not invent the new composition, however, but rather promoted it by having in particular the process modified to prevent the glass from crizzling under the action of humidity.

Owing to a higher density (e.g. 3.0 g/cm^3 for 30 wt % PbO), flint has a high refractive index of 1.60 or more and is in addition more dispersive than crown glass (Abbe number lower than 50). These properties made it valuable in optics especially after the mathematician Leonhard Euler (1707–1783) had theoretically shown in 1747 how chromatic aberration could be corrected, as done by the eye, by a juxtaposition of differently refractive media. Although first unconvinced by Euler’s demonstration, the optician John Dollond (1706–1761) eventually showed in 1758 that he could cancel out the aberration by associating a concave flint and a convex crown lens with focal distances in 2 : 3 ratios. (A similar arrangement had in fact already been realized toward 1730 by the lawyer Chester Moore Hall (1703–1771), who did not publicized it.) Shortly afterward, Peter Dollond (1731–1821),

John’s son, improved the design by inserting a convex flint lens between two concave crown lenses so that a wider field of view was combined with a reduction of another defect, the spherical aberration (Chapter 6.1).

But grinding and polishing of lenses remained a difficult exercise for which the theory also written by Euler found few readers. Empiricism was still predominant. Peter Dollond “makes at once a large number of lenses from both glasses, and combines them until he finds an assortment with which he is satisfied,” was thus told the mathematician and astronomer Jean Bernoulli (1744–1807) during a visit to London in 1769 [30]. National considerations were in addition lurking at a time when Venice was declining and England was benefitting from a monopoly situation for its flint. A nationalistic feeling was thus felt in London by Bernoulli, who commented:

When the glass has been prepared in the glass-works [...], it is rolled into hollow cylinders in which the opticians whom one wants to favour can easily make a choice of the best glass; but after that, one melts the remaining cylinders and out of them one makes flat but rough masses, where no one in the world can see whether or not there are bubbles or streaks in the glass. Foreign artists can hardly flatter themselves to obtain another glass than the latter, and if the maker knows that glass is requested to imitate an invention of his country, it will not be up to him that one gets it as bad as possible.

2.8 Seeing Farther: The Issue of Glass Homogeneity

The general quality of flint remained poor because the usual imperfections of glass were compounded by the difficulties faced to incorporate homogeneously the dense lead oxide at high concentrations, which resulted in glass layers of increasing PbO contents from top to bottom in the melting pots. In the last part of the eighteenth century, the new French and German producers that had entered the market in the meantime met with the same problem. The solution was brought only around 1790 by Pierre-Louis Guinand (1748–1824), a former apprentice carpenter from the Neuchâtel area in Switzerland, through vigorous stirring of the molten batch with the refractory rod he invented (Figure 7). The interest raised by the high-quality lenses of up to 20 cm obtained by the new process led Guinand to be hired in 1805 in Bavaria. There, a collaboration began with the young physicist Joseph von Fraunhofer (1787–1826) who would build in 1824 the first modern achromatic refracting telescope

Figure 7 Guinand's process: stirring of molten flint with a U-shaped iron bar embedded into a refractory mantle made of the same earth as the covered pot [31].

with a 24 cm lens at the Russian Dorpat observatory, in Estonia.

This markedly better flint was thus making it possible to increase the size of lenses to see farther in the universe by gathering more light. Whereas lens diameters were a few cm at Galileo's time, they reached 1.02 m in 1890 at Yerkes Observatory (Wisconsin). But there was a limit in this increase because larger still lenses would have been too heavy to be supported by their edges, and less sensitive for observations in blue light for which long photographic poses (on glass plates) showed their superiority over visual observations. Again, glass was the solution to this problem. To avoid chromatic aberrations, Newton had proposed to collect and focus the light not with a lens, but with a convergent mirror [27, 28]. Although this design allowed William Herschel (1738–1822) to discover 2500 new nebulae (Chapter 7.1), the construction

of large *reflectors* was difficult because a mirror must have a polish four times smoother than that of a lens and is in addition more sensitive to vibrations, thermal expansion, and other disturbances. When a 1.83 m metal mirror was polished in England in 1845, it was thus thought that the limit of feasibility had been reached.

It was a new process of silvering glass developed in 1851 that revived the race for large instruments. Easier to polish than a metal, of more stable dimensions, glass also had the advantage of being able to be stripped of a worn coating and resilvered without great difficulty. With their young but already powerful glass industry, the Americans proceeded rapidly toward very large instruments. In 1917, the Mount Wilson Observatory (California) received from Corning a 2.54 m mirror with which Edwin Hubble (1889–1953) explored the galaxies and discovered the expansion of the universe. Soon after, Pyrex (Chapter 7.6) made it possible to cast in 1934 for the observatory of Mount Palomar (California) a mirror of 5.10 m in diameter and 0.66 m in thickness, which took nearly a year to cool before being polished with a precision in the micron range. It weighs “only” 18 tons (instead of 30) thanks to a honeycomb structure that optimizes weight and rigidity. Until the manufacture in 1976 of the 6-m mirror of the Russian observatory of Mount Pastoukhov (Caucasus), it remained the largest glass piece ever cast.

3 The Enabler of Chemistry

3.1 An Alchemical Tradition

As a technical material, glass was also early put to use along with metal parts in various devices designed by Greek inventors [5], for instance, by Philo of Byzantium (fl. 247 BCE) with his “beautiful and enjoyable vessel” in the form of a “horn with glass hat for filling, siphoning and emptying actions” [32]. In his own *Pneumatics* [33], Hero of Alexandria (first century CE) later followed suit with the variety of his automata and recreational devices that were relying on the force of water vapor and air (Figure 8).

From a more fundamental standpoint, glass represented a dramatic transformation of humble earths into wonderful substances akin to gems (Chapter 10.11). Its fusibility placed it in the same category as the metals then known. It thus attracted the alchemists' interest as a model substance to explain a variety of phenomena related to the philosophy of matter (Chapter 10.4, [34]). It was at the same time playing a great role in practical operations as a substance inert to acids, insensitive to flame, which neither allied nor corroded, and especially allowed the mysterious transformations of matter to be observed visually.

Throughout the four operations of the *Great Work* – decomposition, washing, reduction, and fixation – glass was ready to serve by its plasticity that predisposed its uses in vessels of any shapes (Figure 9). The still, which, for instance, led to the discovery of alcohol, was called the *philosopher's glass*, whereas the crystal-clear

Figure 8 “A Cupping-Glass, to which is attached an Air-exhausted Compartment”: a piece of glassware described in the *Pneumatics* of Hero of Alexandria, section 56 [33].

philosophical egg was a large egg-shaped vessel in which the desired transmutation of base metals into silver or gold was expected to take place, under the right heat conditions, in contact with the mysterious philosopher’s stone. This stone had an incarnate red or ruby color, akin to those conferred to glass by copper and gold (Chapter 6.2). When they actually produced a red copper oxide, alchemists thus believed they had obtained the principle from which gold formed, hence the importance of copper calcinations described in the alchemical literature to prepare red glasses.

Alchemy was then eagerly practiced and developed further in Islam where the idea came that even living beings could be generated in glass vessels. To give a single example, the *Arabic Book of the Cow*, unduly assigned to Plato (~428–347), described the following *experiment* [37]:

For making deadly green scorpions. One should fast for one day, and at the end of the day chew the leaves of wild basilic, bind what was chewed in a glass tube, seal its mouth, and hang it in a dark, damp room which sunlight never enters. After forty days green scorpions will be born in it which, if they sting a man, will kill him.

In the alchemical tradition, the starting material inserted in the glass tube was thus considered to be the semen of the male animal whereas the tube itself was the womb in which the embryo gestated. Such tales did find an audience in Europe when Latin translations of the Arabic literature made them known from the twelfth century. But

Figure 9 One of the earliest representations of alchemical glassware (MS 2327, BN Paris [35]): a thirteenth-century copy of a work by the Greek alchemist Zosimos of Panopolis (third to fourth centuries CE) [36]. From left to right: *tribicos* (top), jar on tripod (bottom), alembic, apparatus similar to a crab and phial on stove.

of more practical interest was then the *urinal*, a kind of glass beaker in which urine was carefully examined by the doctor who sought to find the secret of the patient's health in the turbidity and color of the humor.

Although attempts at making noble metals and animal generation were doomed to failure, the glass paraphernalia of the alchemist not only proved to be valuable when chemistry smoothly replaced alchemy, but was further augmented. To name a few items, the *retort*, *matras*, *cucurbit*, *beaker*, *coil*, *crystallizer*, *funnel*, *test tube*, *watch glass*, *cruet*, *syringe*, or *pipette* attest to this ever-increasing variety of glass chemical vessels (Figure 10). The reasons for this success were well known, explained the chemist and ceramist Pierre Joseph Maquer (1718–1884):

Good glass vessels should always be used in preference to all others, whenever possible, both because they do not give the most active solvents a hold, and do not allow anything they contain to leak out, and because they are transparent, they give the chemist the freedom to observe what is happening within them, which is always useful and interesting. [39]

3.2 The Last Blow to Aristotle's Natural Philosophy

In contrast to Aristotle's cosmology, which had suffered a fatal attack from the telescope, other points of the Aristotelian natural philosophy not only had not been challenged but been supported from experimental investigations made from the seventeenth century. This was the case of the mutual transformations of the four elements – fire, air, water, and earth – through exchange of their respective *qualities* (dry and hot for fire, wet and hot for air, wet and cold for water, and dry and cold for earth). As reviewed by Antoine-Laurent de Lavoisier (1743–1794) [40], distinguished investigators, for example, thought that the transformation of water into earth was demonstrated by the gain weight of plants grown in pots whose own weight did not change, as well as by the white, earthy powder always found in glass vessels after repeated water distillations. The eminent Robert Boyle (1627–1691) was one of the practicing chemists who stated that this *Terrestrial substance* recovered, even after distillation of rain water, led “to suppose the Transmutation itself to be real,” and to conclude that

if the purest Water may be turn'd into Earth, it will not be easie to make it improbable that the other Ingredients of mixt Bodies, which the Chymists call their Hypostatical Principles, are capable of being transmuted into one another. [40]

To Lavoisier, however, the transmutation of water into earth was just “a gratuitous assumption” [41], which he set to disprove with the help of his balance in a famous series of experiments. Of particular importance was the fact that, after repeated water distillations, the weight of the dried recovered deposit was the same as the weight loss of the glass vessel. Among other implications of his observations, Lavoisier concluded

that water does not change in any way in nature, & that it does not acquire any new properties by repeated distillation; [...] That the very substance of the glass itself is subject to solution in water; & that there is, as for all salts, a saturation point, beyond which no further solution can take place. [42]

In other words, the results reported by Boyle and other experimentalist during more than a century, “far from proving the possibility of changing water into earth, would rather lead them to believe that it is unalterable” [42]. At last, the postulate of the mutual transformations of the elements was thus ruled out for good after two millennia of acceptance.

3.3 An Ever-Increasing Usefulness

Ironically, glass had not served chemistry by its much vaunted inertness but by its alterability to ensure the demise of the last vestige of Aristotle's natural philosophy and, therefore, to pave the way to the new system of chemistry that would emerge at the end of the eighteenth century. Glass of course did not lose its privileged place along the way: without it, there would have been simply no chemistry and experimental biology would have also missed a key experimental component. Glass thus kept being strongly praised, as done by Jean-Baptiste Dumas (1800–1884), a pioneer in organic chemistry (and Pasteur's mentor), who stated in his *Treatise of Chemistry* that

what is really characterizing our modern civilization is its use by physicists and chemists in their experiments. An in-depth study of chemistry is not needed to acknowledge that it is thanks to glass that this discipline owes all its advances that have allowed its present theory to be established, so fertile in wonderful applications. [43]

In the same spirit, Dumas' friend Justus von Liebig (1803–1873) explained in his *Familiar Letters on Chemistry* that glass was a well-known and “curious substance” because of “its transparency, hardness, destitution of color, and stability under ordinary circumstances” [44].

Figure 10 Lavoisier's chemical glassware at the end of the eighteenth century. Plate IV of his *Elements of Chemistry* [38], usually considered as the first modern chemistry treatise.

To these obvious qualities, he continued, we may add those “which especially adapt it to the use of the chemist,” namely, that it is unaffected by most acids or other fluids, becomes upon heating more ductile and plastic than wax to take the form required by every vessel and apparatus, and can be nicely combined with cork for connections. Chemical ware had then become made from *hard* Bohemian glass [45], a very homogenous material withstanding high temperatures and resistant to corrosion whose composition typically included 8 wt % CaO, 15% K₂O, and 75% SiO₂ (made from saccharoid limestone, tree ashes, and hyaline quartz mined in large veins). With his *Kaliapparat* made of five glass bulbs, Liebig himself pioneered determinations of the carbon, oxygen, and hydrogen contents of organic substances [45].

This importance of glass was even accrued in the early nineteenth century when glass tubes proved to be valuable vessels for electrolysis experiments thanks to their electrical insulating properties and transparency, which allowed electrode phenomena to be observed directly. The discoveries of alkali and alkaline earth elements (Chapter 10.11) are other examples of the chemical advances made possible by glass in electrical studies. At the same period, chemists began to be trained to blow themselves their glassware. The time of Lavoisier was thus over where “the rich alone could make chemical researches,” noted Liebig, because “the necessary apparatus could only be procured at a very great expense” [44]. Following him, chemists as famous as Jacob Berzelius (1778–1849) or Michael Faraday (1791–1867) also became expert glass blowers in a new tradition that would still be followed by PhD students in many chemistry departments as late as in the 1950s.

At the end of the nineteenth century, another important advance was made through the availability of silica glass (Chapter 10.11), which could be shaped at the very high temperatures required thanks to the new oxy-gas blow-torch [46]. Shortly afterward, the invention of borosilicate glasses (Chapter 7.6) finally provided chemists with ware more resistant to both leaching and thermal shock. In spite of the modern use of disposable (glassy) plasticware (Chapters 8.7 and 8.8), it should thus come as no surprise that inorganic glass is still and will long remain ubiquitous in chemical activities where it has actually found various new uses. Thanks to its lack of absorption bands in the relevant frequency ranges, silica glass has, for instance, become an indispensable auxiliary for a wide range of spectroscopy techniques (Chapter 5.1) in the form of cells and cuvettes for analyses of gases and liquids.

4 Hotness and Air Weight Measured

4.1 Temperature: The Thermometer

The notions of *temperature* and *heat* have remained entangled until the end of the eighteenth century. The eminent naturalist Lazzaro Spallanzani (1729–1799), for instance, believed that over long-enough periods of time, the fire of furnaces would reach an intensity sufficient to melt lava [47]. In thermodynamic terms, the difficulty was of course to distinguish intensive (temperature) and extensive (heat) properties. In a qualitative manner, the former was easiest to define. Dilation of air enclosed in a warm vessel had, for instance, been noticed in Antiquity by Philo of Byzantium or Hero of Alexandria. In a variety of the ingenious or recreational devices actually built described in their *Pneumatics* [32, 33], both of them also put to use the expanding and contracting powers of water upon vaporization and condensation, respectively.

But only toward the end of the sixteenth century was the dilation of air used in *thermoscopes* to measure temperature variations. Galileo himself designed such an instrument made up of a glass bulb, filled with air, and welded to a vertical capillary, filled with wine, immersed at its bottom in a cup of the same liquid. When becoming warmer, the air was displacing the wine meniscus whose position was determined by the temperature increase. For obvious reading reasons, glass was the only transparent material with which the apparatus could be built.

Not only was such a measurement of the degrees of heat or cold relative, however, but it was also sensitive to atmospheric pressure (still unknown at that time). More reliable instruments were thus designed when the first *thermometers* built in the early 1640s in Italy relied on the dilation of water or spirit of wine in glass [23]. Under the auspices of the *Accademia del Cimento* founded in 1657 in Florence by the Great Duke Ferdinand II of Tuscany (1610–1670), many kinds of devices were soon after designed with either vertical capillaries or coils (Figure 11). Important problems were then intercalibration of the instruments and the establishment of temperature scales to which Daniel Fahrenheit (1686–1736), René-Antoine Ferchault de Réaumur (1683–1757), Anders Celsius (1701–1744), and Antoine Baumé (1728–1808) would attach their names.

4.2 Air Pressure: The End of Horror Vacui

At the beginning of the seventeenth century, it was curiously observed in Tuscany that any siphon (or suction

Figure 11 The diversity and Venetian style of the vertical and spiral glass thermometers designed in Florence in the seventeenth century. Photo Franca Principe, Museo Galileo, Florence, inv. 20477.

pump) empties itself when the height of the water column exceeds about 18 braccia (10 m). The physicist Giovanni Battista Baliani (1582–1666) understood this effect as the result of the gravity of the air becoming insufficient to compensate the weight of water at both ends of the siphon. To check experimentally this conjecture, the mathematician Evangelista Torricelli (1607–1648) had the idea of taking a straight tube as the simplest form of siphon. To make direct observations possible, he turned to glass tubes filled with liquids denser than water, namely, sea water, honey, and finally mercury. When a tube filled with mercury, closed at one end, was immersed into a tub of the same metal at its other end, Torricelli indeed observed that the level of mercury was higher than in the tub. But was the empty space left at the top of the tube filled with mercury spirits or imperceptibly rarefied air? Repeating his experiment with devices of different lengths, inclinations and shapes, Torricelli found that the mercury was in each case rising to the same height (Figure 12). In two letters sent in 1644 to a friend to describe his experiments [49], he thus concluded that the force raising the mercury was external to the tube. As postulated by Baliani, therefore, this force originated

Figure 12 The pressure exerted by the atmosphere as indicated by the same height of mercury in glass tubes of different sizes, shapes, and inclinations partially immersed in a mercury tank. Engraving from [48].

in the gravity of the air and Torricelli also thought that it was changing because the air was “at times heavier and thicker and at times lighter and more rarefied.”

Torricelli's letters were widely circulated. Attempts were, for instance, made at duplicating his experiments in Paris, but the glass tubes drawn there did not resist the pressure exerted by 3 ft of mercury because their quality did not match that of those made by the Venetians working in Florence. Until the nineteenth century, tubes of large and small sections would be drawn from slightly cooled and very hot glass, respectively. In both cases, the blower shaped a gob in the form of a cylinder on which an aid stuck another gob. When the two workers moved evenly away from each other, the tube began by the blower lengthened regularly by taking glass from the gob carried by the aid while a third worker held a fan to cool down the tube where the desired diameter was achieved (Figure 13). Compared with the ware used in chemistry, the long glass tubes needed for quantitative experiments thus raised difficult technical problems to be straight and of uniform section and mechanically strong enough for not shattering under the weight of mercury.

Figure 13 The traditional procedure for drawing glass tubes from two different gobs [31], which could be as long as 100 m.

Thanks to the better quality of Norman glass tubes, it was in Rouen that Torricelli's observation could be repeated in France on October 1646 by a team that included the young Blaise Pascal (1623–1662) and his father. To demonstrate the existence of vacuum, Pascal then performed experiments with a variety of devices, including glass tubes up to 50 ft long. Part of them were probably *thought experiments*, but a particularly significant result actually obtained was that of the “vacuum into vacuum” check whereby the mercury of a glass tube placed in a vacuum did not rise at all.

In the excitement generated by Torricelli, similar experiments had been made elsewhere. But Pascal was the one who made the most of them, first in a short letter [50] and then through the observations performed at his request in 1648 of the decrease of the height of mercury in a glass tube carried from the city of Clermont-Ferrand (elevation 358 m) to the top of the nearby Puy de Dôme (1465 m) while another tube was left in town to allow possible fluctuations in air gravity to be detected during the experiment. “It is quite certain that there is much more air that presses on the foot of the mountain than there is on its summit,” remarked Pascal [51]. And since “one cannot well say that nature abhors a vacuum more at the foot of the mountain than at its summit,” Pascal concluded that the observed variations definitely ruled out the antique *horror vacui*: “the weight of the mass of air is the true cause of all the effects hitherto ascribed to that imaginary state” [52]. Thereafter, the *continuous experiment* made from 1649 to 1651 at Pascal's request constituted the very first series of barometric observations,

which signaled the beginnings of meteorology in the modern sense of the term.

Pascal did not stop at this point. As he stated early [50], the effects caused by gravity and air *pressure*, a term that was for the first time used in its modern sense, illustrated the direct link between the study of vacuum and the new science of *hydrostatics* that was emerging with his *Treatise on the Equilibrium of Liquids* [52], completed in 1654 but published posthumously in 1663. Because of the principle that “liquids weigh in proportion of their height,” Pascal invented along the way the hydraulic press to intensify forces very simply (Figure 14). He also drew a number of consequences of this principle. It was, for instance, the *hydrostatic* nature of pressure in a liquid that made aquatic animals equally pressed on all sides and, thus, not feeling the weight of water. Among other things, Pascal could in addition estimate the weight of the whole atmosphere because the air at sea level was weighing as much as water 31 ft and 2 in. high. With some assumptions to account for the decreasing density of the air with increasing elevation, his result of 8.285×10^{18} pounds – derived from the height of mercury in a glass tube – was an impressive first step toward today's value of 10.48×10^{18} pounds (1 pound = 0.49 kg) [52]!

4.3 The Springiness of the Air

Since vacuum did exist, investigators rushed to study its most varied effects. Torricelli had himself tried to check whether bugs survived in a vacuum, but the mercury of

Figure 14 Pascal's hydraulic press [52], "a vessel full of water, sealed on all sides and provided with two apertures, one of them one hundred times as large as the other. If a perfectly fitting piston is adjusted to each, one man pressing on the smaller piston will exert a force equal to that of one hundred men pressing on the larger, and will exceed that of ninety-nine men doing the same. And whatever the relative areas of these apertures, if the forces exerted upon the pistons are in the same ratio as the areas, they will balance one another. Whence it follows that a vessel filled with water is a new mechanical principle and a new machine that will multiply forces to any amount desired; for a man by this means will be enabled to lift any weight that another may propose."

his glass tubes killed them too rapidly. Thanks to their tightness to air and transparency, glass vessels were of course the ideal complements of the vacuum pumps. These were designed with much inventiveness [23], in particular by Hooke when he was an assistant to Boyle. It was with Hooke's pump that Boyle observed in glass

vessels the elusive effects of a good vacuum: sound is, for example, no longer propagating, water is boiling at room temperature, whereas life and flame badly require air to be sustained [53].

Already in Antiquity the rebound of inflated balls had shown that air is an elastic body with a strength that, contrary to that of a spring, does not weaken. Again assisted by Hooke, Boyle studied this elastic force (the *springiness*) by measuring the volume of the air enclosed in a U-shaped glass tube when pressure was slowly increased through small mercury additions. From his results, Boyle concluded only in the second edition of the book [53] where his measurements were reported that "common air, when reduced to half its wonted extent, obtained near about twice as forcible a spring as it had before," and so on (Figure 15). While further work was done to check whether this law remained valid at higher pressures, as guessed by Boyle, the physicist Guillaume Amontons (1663–1705) investigated the effects of temperature on gas pressure [54]. Better known for the laws of friction he established, Amontons was also one of the first theoreticians of heat engines. His measurements indicated that Boyle's law was valid only at constant temperature as "unequal masses of air increase almost equally the force of their air spring by the same amount of heat." On this basis, Amontons invented the first gas thermometer and foresaw the intensive nature of temperature by noting "that unequal masses of air acquire equal spring forces by the same degree of heat."

But the remarkably fruitful physical career of mercury glass tubes was not over yet. Boiler explosions became increasingly frequent with the empirical development

Figure 15 Boyle's mercurial experiments as made with "a long glass-tube, which by a dexterous hand and the help of lamp was in such manner crooked at the bottom, that the part turned up was almost parallel to the rest of the tube" [53]. (a) Tube of maximum length of 6 ft (1.8 m). (b) Constancy of the product of pressure (P) and volume (V) as represented anachronistically by a $P - 1/V$ plot (P and V expressed in inches of mercury in glass tubes; 1 in. = 2.54 cm), the remarkably small scatter in the data pointing to tubes of uniform enough sections.

of the high-pressure steam engine at the beginning of the nineteenth century. To impose safety precautions to these machines, the French government asked in 1823 the Académie des sciences for means of preventing accidental loss in men and property. Led by Pierre-Louis Dulong (1785–1838) and François Arago (1786–1853), a committee determined that the main risk originated in the lack of proper safety valves because the vapor pressure of water was not known under the relevant conditions. As they stated, “no physicist had hitherto dared to make experiments at pressures higher than 8 atmospheres because of the extreme difficulty of these kinds of research, and of the danger that accompanies them” [55].

Willing to perform measurements as accurate as possible, the Paris Academicians relied on the most difficult, but “most exact method,” namely, the direct measurement “of the mercury column able to equilibrate the elasticity of the vapor” up to 30 atm. For this purpose, glass tubes 2 m in length and 5 mm in diameter were assembled over a 20–25 m height to serve for measurements eventually performed up to 224 °C and 24 atm only because of boiler leaks at higher pressures. After having tried various empirical relationships, the Academicians fitted an equation to their results that later proved accurate up to more than 100 atm (Figure 16). In a sibylline way, they concluded that

only people accustomed to great experiments in physics can appreciate the enormity of the task that was imposed upon us, to which nothing comparable would be found in our records, and which necessitated on our part a dedication that the Academy perhaps had not the right to require from any of its members.

4.4 Sap and Blood Barometry

Even biology did not escape mercury glass barometry. It was a disciple of Newton, the Reverend Stephen Hales (1677–1761), who pioneered such measurements to determine the physical principles of the circulation of sap, in plants, and blood, in animals. In 1727, he described in his *Vegetable Statics* [56] how to measure the rise of sap as a function of season and time of day (Figure 17). A good century after the discovery of blood circulation by William Harvey (1578–1657), Hales then reported in 1733 in his *Hæmastatics* the research begun in 1706 on blood pressure [57], which he had long interrupted out of disgust for cruel experiments. His main aim was to discover “whether the blood, by its mere hydraulic energy, could have a sufficient force, by dilating the fibres of the acting muscles, and therefore shortening their lengths, to produce the great effects of muscular motion.”

Figure 16 The key to the safety valve of steam engines [55]. (a) The vapor pressure of water as a function of mercury pressure in glass tubes; Eq. $T(^{\circ}\text{C}) = (P^{0.2} - 1)/0.7153$ fitted to the data. (b) The pressure–volume relationship of the vapor along this curve.

Figure 17 Pressure as a probe of the physiology of plants in experiments made by S. Hales to determine barometric depressions in vascular plants [56]. Ascent (z) of the mercury contained in tubes resulting from the absorption of the water filling the glass vases tightly attached to the root of a pear tree (Figure 10), the stem of a young apple tree (Figure 11) and the branch of a vigorous apple tree (Figure 12).

Hales, for example, measured the pressure in the crural artery of a mare, immobilized on her side, in which a 9-ft (2.7 m) long glass tube filled with mercury was implanted through a brass pipe.

In further measurements, Hales observed that blood pressure is much lower in veins than in arteries, that it is characteristic of every species (dog, ox, sheep, fallow deer) and, in addition, that it probes the cardiac condition of an animal. But this force of arterial blood in capillaries was far too low to cause muscle contraction, concluded Hales who suggested with insight that “this hitherto inexplicable Mystery of Nature must therefore be owing to

some more vigorous and active energy, whose force is regulated by the nerves” through electrical effects. The relevance of electricity to neuromuscular processes was thus surmised by Hales, who pointed out that an electrical virtue could indeed be conveyed over great length even through a human body.

5 From Electrostatics to Subatomic Physics

5.1 The Beginnings of Electrostatics

In the burst of scientific activity of the early eighteenth century, much attention was actually paid to electric phenomena, which were clearly representing a *terra* still largely *incognita* that it was now time to explore. These phenomena had been termed *electric* by the physician William Gilbert (1544–1603) because of the curious power acquired upon rubbing by amber (*elektron* in Greek, *electrum* in Latin) to attract light objects, which had already been known in Antiquity. By a twist of history, glass tubes were at the roots of a renewed interest in these phenomena. The astronomer and priest Jean Picard (1620–1682) had already noticed the light emitted in a vacuum at the top of a mercurial tube jostled in the dark, but a really strong interest in the phenomenon arose only after Francis Hauksbee (~1660–1713) [58] and Pierre Polinière (1671–1734) [59] independently reported in 1709 their experiments on the strong luminescence emitted by these tubes upon rubbing.

Confusion quickly resulted from the wealth of observations recorded when various kinds of materials were rubbed although an important distinction was made by the dyer Stephen Gray (1666–1736) who discovered that bodies were either conducting the *electric virtue* of a glass tube or not [60, 61]. Interestingly, glass again played a pivotal role in the clarification of this confusion in 1733. From well-designed series of experiments, the polymath Charles Du Fay (1698–1739) understood in 1733 that there are in fact two kinds of electricities [62, 63]. Creating a nomenclature that would hold until the end of the nineteenth century, he termed them *vitreous* (positive) and *resinous* (negative), not because they were yielded only by glass and copal (a kind of clear amber) but simply because he discovered them with these two substances. And Du Fay implicitly made use of the philosophical *Principle of sufficient reason* to add: “If there are in nature only these two kinds of electricity, which seems quite likely to me, because one attracts what the other repels, I don’t really imagine what effect a third one could have” so that all bodies, “with the exception of metals, will be in one or the other of these two classes” [62].

It would take a long time to understand that glasses are *dielectrics* (another term coined by W. Whevell), i.e. they are polarizable electrical insulators. Without knowing it, mid-eighteenth-century *electricians* thus took advantage of this feature in two important devices. One was the *Leyden jar*, the first capacitor made up of two metal foils cemented inside and outside a glass jar with which voltages of up to 60 kV could be reached by friction, and which made controlled accumulation and discharge of electricity possible. The other was the electrostatic machine (Figure 18) with which voltages of up to 330 kV were obtained at the end of eighteenth century. These machines came in many kinds [65] although they all involved rubbing of glass in the form of globes, cylinders, or disks whose largest diameter of 1.65 m eventually reached what was in fact the size limit achievable with the crown process (Chapter 10.8). Especially with the electrostatic machine, all effects that could be imagined were studied, raising considerable interest in the public because of the spectacular features observed (Figure 18), in particular when the electrical conduction of the human body was put into play to produce sparks or let participants feel the delicious thrill of discharges.

5.2 The Womb of Subatomic Physics

Following the invention of the electrical pile by Alessandro Volta (1745–1827) in 1800 and the discovery of the interaction between electricity and magnetism by Hans Christian Ørsted (1777–1851) in 1820, the physicists' interest shifted to the new field of electromagnetism to which metal conductors, and not glass vessels, were actually relevant. But glass did come back to the fore in the second part of the nineteenth century after improvements in mercury pumps had made it possible to reduce further the pressures obtained in evacuated tubes. Of particular interest was the electrical conduction in rarefied gases in relation to the properties of *ether*, the elusive fluid filling all space whose existence was postulated for the propagation of electromagnetic waves. According to some physicists, for example, a complete vacuum should have been a perfect electrical conductor since the lack of any matter would have allowed the ether to flow without any resistance.

In view of the importance of the problem, much effort was made, in particular by the physicist and glass blower Henrich Geissler (1814–1879), to improve *discharge*

Figure 18 A typical eighteenth-century electrostatic experiment made by Christian August Hausen (1693–1743) at Leipzig [64]: *vitreous* electricity produced by the lady's hand rubbing the rotating glass disk, transmitted from the shoe to the arm of the fellow (suspended by insulating silk threads to the ceiling, as pioneered by S. Gray [60]), and finally to the girl who is attracting small gold leaves with her hand, adumbrating in this way the electroscope. While the girl is standing up on an isolated pad, the lady carries off with her body the *resinous* electricity to the ground. The involvement of these two women and of the churchman, who is turning the crank of the electrostatic machine, illustrates the wide interest of the public at large of the period in such experiments.

Figure 19 The good use by Crookes of transparency and other properties of glass: the observed rotation of a mica toothed wheel (*ef*) when the rays emitted by a cup-shaped cathode (*ab*) toward an absorbing mica plate (*cd*) are deviated upward by the field of a magnet (*g*) [67].

tubes, i.e. evacuated glass tubes through which two electrodes are welded (the ancestors of the neon lighting tube, see Chapter 6.9). When a voltage was applied, electrical transport was signaled by a bluish glimmer extending from one electrode to the other accompanied by a greenish light appearing at the end of the tube opposite from the cathode. This emission was thus termed *cathode rays* (cf. [66] for a detailed account). An important step toward understanding their nature was made when, taking advantage of the pressures as low as 10^{-6} atm he could reach, the physicist William Crookes (1832–1919) designed a variety of experiments thanks to which he observed that these rays are emitted perpendicularly to the cathode, are deviated by a magnetic field (Figure 19), induce a strong luminescence when impacting the opposite side of the tube, and especially that a metal leaf placed along their path produces a shadow of the same form (Chapter 6.10, Figure 3). Crookes thus suggested in an 1879 lecture that a new type of corpuscular radiation could exist independently of electromagnetic waves [67].

Further work showed that these rays impress photographic plates and carry negative electric charges. When investigating them, the physicist Wilhelm Röntgen (1845–1923) noticed that an external fluorescent screen placed at some distance from the tube emits a luminescence whose intensity increases if brought closer to the tube. When putting his hand between the tube and the screen, Röntgen had then the striking surprise to see his own bones. He had discovered a new kind of radiation [68], which would be termed X-rays because of their

enigmatic nature. This strange radiation indeed traversed glass tubes but did not undergo refraction nor was deflected by a magnetic field although, as Röntgen also showed, it was partially absorbed by all substances in varying degrees. The impact of this discovery was so strong, even on the general public, that glass tubes of any shape were designed to investigate further X-rays and their most various physical, chemical, and biological effects (Figure 20).

But the cathode rays themselves were remaining enigmatic. In Cambridge, measurements of their deflection by electric fields by the physicist Joseph J. Thomson (1856–1940) indicated that they involve particles lighter than atoms. By deflecting the rays in a glass tube with both electric and magnetic fields (Figure 21), Thomson then determined the ratio of their charge and mass and, in 1899, these two parameters separately [71]. Interestingly, these negatively charged corpuscles were the same regardless of the metal of the cathode and their mass was 2000 times smaller than that of the lightest ion, hydrogen. Thanks to ever higher vacua that allowed electrons to travel without undergoing collisions along their path, a dogma had collapsed: the atom was not the smallest unit of matter. These corpuscles took on the name earlier proposed in 1891 by George Stoney (1826–1911) for the fundamental unit of electric charge, the *electron* [72].

In his 1879 lecture, Crookes had said that “in studying this fourth state of matter we seem at length to have within our grasp and obedient to our control the little

Figure 20 The great many types of X-ray tubes designed during the year 1896 alone [69].

indivisible particles which with good warrant we suppose to constitute the physical basis of the universe" [67]. Crookes' intuition was thus vindicated by Thomson. When combined with transparency, tightness to gas and shapability, the high electrical resistivity, weldability

with metals, and penetrability by electric and magnetic fields of glass had surreptitiously led from electrical conduction in gases to subatomic physics. At last, the alchemists' picture of glass vessels as wombs for wonderful phenomena had come true in some unexpected ways!

6 Perspectives

Has it ever been estimated how much of the humanity's literary, artistic, or scientific achievements is indebted to two small pieces of glass resting on the nose and held to the ears by two temples? The answer would illustrate most simply the impact that glass have had upon man's activities throughout the ages. Regarding science, the most important conclusion to be drawn from this selective review is that, in none of its uses, glass could have been replaced by another material. The conclusion is anything but new. When celebrating glass in the flowery language of his time, the Russian polymath Mikhail Lomonosov (1711–1765), for example, marveled on the way in which studies of the discharge of electricity accumulated by friction on glass had given rise to the lightning rod:

Turning about, the Glass globe gives off blows with brilliance, resembling thunder and lightning with their crashing and glare", so that "the same power of roaring clouds which brings on darkness issues also from the movement of Glass! Knowing the laws discovered by Glass, we thus can turn lightning away from our dwelling places. [73]

Glass in fact nicely illustrates the statement often made that the history of science is largely that of scientific instruments thanks to whole new fields of inquiry repeatedly opened. Although only a few individuals could be mentioned within the scope of this chapter, the large numbers of people who collaborated or competed to integrate glass in these instruments is most simply attested to

by the variety of designs that appeared right after the invention the telescope, the microscope, or the discharge and X-ray tubes. In this respect, diversification in glass composition and improvements in glass making also played a major role as illustrated by flint glasses and the Guinand process whose benefits for astronomy were immediate (Figure 22).

Figure 22 Glass technology in the service of astronomy: following Dollond's work, the introduction of achromatic lenses for refractors and the marked increase of their sizes then triggered by Guinand process. Open circles: continental Europe; solid circles: United Kingdom; crossed squares: rest of the world (mostly USA). Data from [74].

After a time lapse of a few centuries between the first practical applications of optics in spectacles – the earliest technological invention made in Occident – glass became the most powerful weapon against the Aristotelian worldview and its *horror vacui*. The purely qualitative nature of Aristotle's natural philosophy found in addition itself under attack since varying degrees of hotness became at last distinguishable at the same time that pressure was defined and measured. In Leeuwenhoek's expert hands, a tiny globule of glass became shortly after what has probably been the simplest scientific instrument ever designed with which epochal observations were nonetheless performed. Although barely more complicated, the mercury glass tube also lent itself to ground-breaking observations; with Pascal's hydraulic press, it even gave rise to one of the very first practical applications directly derived from scientific theory in modern times.

Following the initial outburst of the revolutionary seventeenth century, advances might seem to have slowed down afterward. The actual picture is more subtle, however, as new fields of research continuously emerged as a result of further technological progress. It was, for instance, only at the beginning of the nineteenth century that the small lenses of the compound microscope could be made achromatic [5]. Histology or microbiology – and its considerable impact on medicine through the discovery of pathogen microbes – then benefitted much from the ensuing sharper images and higher magnifications.

Likewise, a rigorous science of rocks came on the scene in the 1850s once the discovery of the polarization of light made it possible to identify rock-forming minerals from their specific dichroism. The first advances were made by William Nicol (1768–1851) who designed calcite (CaCO_3) prisms with which light could be conveniently polarized in a known direction of the microscope [75]. Nicol then had the idea to observe opaque rocks in very thin, and thus translucent, sections glued on glass slides and protected by glass coverslips. Slightly later, however, it was Henry Clifton Sorby (1826–1908) who fully realized the potential of the technique. He thus really launched the new science of *petrography* thanks to the possibility of identifying minerals and characterizing their mutual relationships in a given rock [76].

Such observations were soon to play also a fundamental role in glass science in conjunction with the quenching method [77] to determine most phase diagrams of interest from simple to complex systems (Chapter 10.11). The liquidus temperature is signaled by the appearance of tiny, generally birefringent crystals. Under the petrographic these crystals are in general readily detected in the glass groundmass of the quenched charge and, in solid

solutions, their optical properties may in addition allow their composition to be estimated. The solidus is in contrast characterized by the disappearance of the glass phase within a crystalline-phase assemblage, which is, however, more difficult to observe.

The antique glass vessels went themselves through completely new transformations that took implicitly advantage of the dielectric glass properties to become, for instance, large capacitors or discharge tubes. Although the relative permittivity of crown glass of about 5 is not outstandingly high, no other substance yield such a solid, isotropic, electrically insulating, mechanically strong, and readily shaped material. Since then, new ways to shape glass or modify its composition have resulted in other original advances. In this respect, a most important achievement has been the glass electrode for pH measurements, which combines physical and chemical effects so complex that they are still not fully understood (Chapter 5.8). As for optical fibers for the visible range (Chapter 6.4) or infrared optics (Chapter 6.5), their applications to chemical analyses, remote control, or communication technologies are too well known to be reviewed here, even briefly.

Finally, one should not overlook less visible but numerous applications of glass, for instance, in fibers (Chapter 1.6) reinforcing the printed-circuit boards that are nowadays ubiquitous in scientific computing and instrumentation. A quite different use is that of silica aerogel, which has proven valuable as a nonpolluting net to trap tiny extraterrestrial matter traveling in the solar system and bringing it back on Earth for study (Chapter 8.3). Thin films (Chapter 6.8) have also become highly relevant to scientific activity as recently illustrated by the detection of gravitational waves. With a modified Michelson interferometry, the sensitivity of the detectors has relied on silica glass mirrors coated with multi-layer thin films (Chapter 6.8) to reduce reflection losses to ppm levels. Such an appropriate reduction has been achieved with ion-beam sputtered multilayers of amorphous SiO_2 and TiO_2 -doped Ta_2O_5 [78]. From a thermodynamic standpoint, these materials are also of great interest because the structures of related SiO_2 - HfO_2 and SiO_2 - ZrO_2 coatings conform to simple predictions, which has suggested that “a transient, possibly liquid-like metastable state is reached during film formation” [79]. These coatings thus exemplify the never-ending adaptation of glass to new scientific enquiries, which is now taking advantage not only of hitherto unusual composition domains but also of new synthesis processes. Others will likely follow, a case in point being hybrid organic–inorganic amorphous materials whose original properties are now raising so much interest (Chapter 8.9).

Acknowledgments

Warm thanks are due to J. Dyon for figure drawing and to R. Conradt, R. Kerner, J.F. Stebbins, G. Strano, and A. Takada for their careful reading of this chapter and thoughtful suggestions.

A History of Glass Science

Pascal Richet

Institut de Physique du Globe de Paris, Paris, France

1 Introduction

What is glass? And what is peculiar to this form of matter to justify the existence of a specific *Glass science*? In a glass history that began about three millennia and a half ago, both questions have been making sense only in the last century. Whether glass would have been defined in terms of structure or of properties, experimental and theoretical means were of course lacking to arrive earlier at anything resembling modern standpoints. As a material, however, glass did not escape reflections from savants throughout the ages even though its making was remaining an empirical practice. The present contribution will try to make it clear for the five broad, overlapping periods that have been distinguished with the part of arbitrariness and lack of comprehensiveness inherent to short historical accounts. It will thus complement to the chapters devoted to early technology (Chapter 10.9) and to the scientific advances made possible by glass (Chapter 10.10).

Beginning in Antiquity, the first period lasted until the Middle Ages. The most obvious features of glass were its transparency or its vivid colors, which made it akin to gems, and its production from a melt, like that of metals. From the Near East to the Latin West, this dual kinship with precious stones and metals thus remained of particular concern during about two millennia. In the early modern period, glass became the subject of a different kind of rational enquiry. Experiments were made to understand some fundamental properties of matter at a time when the dramatic advances in the exploration of the universe made possible by glass lenses (Chapter 10.10)

led to the first speculations on the microscopic constitution of glass-forming liquids.

From the late eighteenth century, a few decades then heralded the entry into a scientific age in the modern sense of the term. This change was felt by the glassmakers of the period as illustrated in 1791 by the *Essay on the Art of Glassmaking* where the chemist Pierre Loysel (1751–1813) stated that

Glassmaking is, among all the arts, the one that can be rigorously submitted to the principles determined by physics, the one that, therefore, can reach the greatest precision, but it requested an observer who would be as familiar with all its processes as instructed in physics. [1]

In fact, it was not so much physics than chemistry that was about to influence glassmaking most as exemplified in 1810 by the *Attempt to Establish the Art of Glassmaking on Scientific Principles* authored by Aldolph Ferdinand Gehlen (1775–1815) who explained how Glauber's salt (sodium sulfate) could be used as a new source of soda [2, 3]. Until then, a glass could be basically characterized only by its density and index of refraction. Hence, the great novelty was the concept of *chemical composition* that resulted itself from the notion of *oxides*, which replaced that of *earths*, and the discovery of the relevant chemical *elements*. In parallel, a new attention was paid to the relationship of glasses with crystals, which made kinetics entering the picture of both glass formation and crystallization.

Following the first systematic measurements of physical properties, a specific *glass science* was finally born in the 1920s when consistent evidence pointed to the existence of a glass transition and experimental means became available to study disordered atomic structures. Since then, glass science has grown tremendously as is

obvious to any reader of the *Encyclopedia* and summarized in an extensive bibliographic study [4]. Hence, this fifth and last period will not extend beyond the mid-twentieth century to avoid unnecessary overlap with other chapters. Owing to an apparent lack of any in-depth historical study of Glass science in the literature, this chapter will nonetheless be longer than others and its bibliography more detailed, as it must be in any such account. In preamble, however, it may be useful to review briefly how the definition of glass has evolved in response to the advances made in the understanding of this material, which is now termed *structural* glass to distinguish it from the newer spin, orientational or vortex glasses.

2 Glass: An Impossible Definition?

Traditionally, glass was defined by the manner in which it was made. It “is a more or less transparent material, coloured or colourless, shiny, fragile, smooth in its fracture, & which is produced by the fusion of vitrifiable stones or earths from saline, alkaline & metallic lime substances” [5], asserted in 1774 Antoine Baumé (1728–1808), best known for his work on thermometer intercalibration and the invention of the *areometer* for measuring the densities of liquids. Half a century later, the chemist Louis Jacques Thénard (1777–1857) stated more simply in an influential treatise that “Glass is a product one obtains by exposing a mixture of silica and different substances, most of the time very fusible, to the action of a violent and sufficiently continuous fire” [6].

These definitions could have already been given in Antiquity. Perhaps the most detailed one was that of Theophrastus (~371–287), Aristotle’s friend and successor as head of his school, the Lyceum. After having noted in his treatise devoted to stones that “earth indeed may undergo processes of melting, softening and hardening again,” Theophrastus added: “if, as some maintain, glass is made from vitreous earth, so too it is firing that causes this earth to become glass” [7]. As made by Jean-Baptiste Dumas (1800–1884) for sugar, sulfur, and arsenic oxide, however, other kinds of substances were already regarded in the nineteenth century as vitreous not from their chemical composition and mode of synthesis, but from their luster, translucency, shapability, or conchoidal fracture [8]. But chemistry was playing other tricks. From silica, silicon was first prepared in the form of a brownish powder by Thénard himself and Joseph Louis Gay-Lussac (1778–1850) through reaction of *siliceous hydrofluoric acid* (silicon tetrafluoride) on potassium [9]. But the two friends did not realize that they had isolated a new element and still less that it was in an amorphous state.

Considering such a new substance as vitreous would have thus led to abandon any convenient macroscopic criteria to characterize a glass. Selenium, which was discovered in 1818 by Jacob Berzelius (1779–1848) [10], was especially interesting in this respect because it existed as both an *amorphous* powder and a *vitreous* form, which were rapidly shown to be identical [11]. In addition, selenium had the original property observed in 1851 by Johann Wilhelm Hittorf (1824–1914) to “melt” without any heat effect [12], and was found in 1871 to be highly refractive and dispersive with an index of refraction varying from 2.65 to 2.98 [13], which illustrated considerable differences in physical properties with the traditional silicate glasses.

Alternatively, the need of annealing might have looked typical of glass. As explained by Baumé,

When the glass cools quickly, the two inner and outer surfaces of the pieces first take on all their strength, and then retreat: but the middle of its thickness is still red and soft; it is in a state of compression; it forms a spring that remains in a state of tension, and is always ready to break the obstacle that hampers it; this is what happens to all glass vessels that are a little thick, and have been badly annealed. [5]

Regardless of this particular interpretation, an “annealing” criterion to define glass would have been irrelevant anyway to amorphous substances not prepared in large pieces whereas the need of slow cooling was not unique to glass. It was also required for many ceramics as a result of the volume change at the α – β transition of quartz, which would be discovered only at the end of the nineteenth century by Henry Le Chatelier (1850–1936).

In a closely related modern variant, glass has been defined as a substance whose second-order thermodynamic properties (heat capacity, thermal expansion coefficient, and compressibility) vary abruptly in a narrow temperature interval upon heating. But this criterion is not generally valid since solid phases akin to glasses produced vapor deposition (Chapter 3.14), pressure-induced amorphization of crystals (Chapter 3.10), or sol–gel reactions between starting organic liquids (Chapter 8.2) may crystallize or decompose before undergoing a glass transition. As a matter of fact, even some silicate glasses quenchable at not extreme rates (e.g. Na_2SiO_3) crystallize rapidly hundreds of degrees below their estimated glass transition ranges.

Alternatively, glass has been defined in terms of structural disorder at the atomic scale, which is making sense in view of the tight connection between this disorder and typical macroscopic features of glass such as unlimited

shapability, lack of grain boundaries, mechanical strength, or extent of solid solutions. From a purely material standpoint, glass thus is commonly said to be a substance deprived of the long-range order of crystals. Because a good definition must be positive and not negative, however, one is then faced with the problem of stating the kind of order existing in glasses, which is known to lack a universal solution.

There nonetheless seems a possibility to conclude this discussion positively. Glasses are *solids*, i.e. substances whose atoms occupy essentially fixed positions. At any scale, they are *a-morphous* in the original sense of the term, which means that they are deprived of any characteristic shape. Compared with crystalline solids, they have in addition an original feature first reported for a variety of silicate glasses in 1845 by Eugène Chevandier (1810–1878) and Guillaume Wertheim (1815–1861), in the case of density and elasticity, which is that their properties differ depending on whether they are quenched or annealed [14, 15]. It is thus tempting to define very simply a glass as a macroscopically homogeneous amorphous solid whose properties (physical, chemical, or structural) vary with its preparation conditions; this definition in particular implies that internal thermodynamic equilibrium does not obtain since knowledge of two state variables such as temperature and pressure is not sufficient to characterize the state of the material.

3 The Origins

3.1 The Middle-Eastern Beginnings

Genuine glass pieces appear in the archeological record in the sixteenth century BCE, i.e. in the Late Bronze age (Chapter 10.2). Regardless of the place(s) where bulk glass was initially made and the sequence of events that led to its production, it is obvious that ancient craftsmen were good observers; otherwise, ceramics, metallurgy, and glassmaking would not have developed as they did over the centuries. Either in a fortuitous way or by trial and error, much experimentation took place to identify the raw materials with which definite goals would be achieved.

Siliceous sand and plant ashes were easily recognizable sources for glassmaking but how *trona* ($\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2 \text{H}_2\text{O}$), the mineral improperly called *natron* (actually $\text{Na}_2\text{CO}_3 \cdot 10 \text{H}_2\text{O}$), came to be used and was mined is not known [16]. In glasses, its earliest chemical signatures date back to the beginning of the first millennia BCE [17]. Natron had already long been used for glazes, however, and from Sumerian times it also served a great many purposes in the urban settings of Mesopotamia, as condiment, soap, or product for the embalming of mummies [18], so that a fortuitous reaction with sand in

the way described by Pliny [19] (Chapter 10.0) might have been possible.

The selection of the all-important coloring agents was more tricky because of the differing hues of the raw materials and finished products. The mastery achieved in this respect is nonetheless revealed by the variety of colors yielded by metals such as copper (red and blue-red), iron (black, brown, and green), antimony (yellow), cobalt (blue), or tin (white) ([20], Chapters 10.2 and 10.3). As, for instance, noted by Theophrastus, “A most peculiar earth is that which is mixed with copper, for it not merely melts and mingles with the metal, but also has the remarkable power of enhancing the beauty of its colour” [7]. By observing that small changes in raw materials could result in marked color differences, ancient glassmakers unknowingly discovered how a given property of a material could be varied almost at will in a continuous solid solution. In this way, Mesopotamian glassmakers replicated obsidians, which were thus distinguished depending on whether they were “genuine” or “from the kiln” [20]. In addition, they produced synthetic basalt by firing local silt without apparently recognizing its kinship with the real rock, which was extensively brought from the Zagros and High-Mesopotamia mountains to make steles and statues in Assyria and Babylonia [21].

Because the first glassmakers were by definition entering an uncharted territory, the uses they found for the new material developed along with their understanding of its properties and, especially, of its shapability, which distinguished it clearly from metals and ceramics (Chapter 10.5). It was a well-established Mesopotamian tradition to keep written records of all activities so that the technical nature of some tablets was not particularly remarkable in itself. The fundamental importance of what we term *viscosity* was thus recorded in cuneiform tablets from the fourteenth or twelfth century BCE from Nineveh, found in the library of the Assyrian King Ashurbanipal (r. 668–~628), advising the glassmaker to observe how droplets of glass were sticking to the tip of the rake used to stir the melt.

Mesopotamian glassmakers were thus familiar with stirring (to achieve chemical homogeneity) as well as with grinding and sintering, a process already long familiar to ceramists. They were aware of the deleterious effects of fumes (through vapor-melt interactions) and thus kept recommending “You keep a good and smokeless fire burning.” They used bellows to achieve sufficiently high temperatures and also knew that the color obtained (through redox reactions) depended on whether their pots were covered or not and the door of their kilns open or closed. Glassmakers also mastered quenching procedures by dipping or immersing glass pots in water, and annealed their pieces to prevent them from breaking spontaneously on cooling.

As would still be exemplified by the *venturina* production in seventeenth-century Venice (Chapter 10.7), glass-making operations were nonetheless tricky and not necessarily reproducible. To ensure success through the protection of gods, specific rites were practiced as documented by seventh-century BCE tablets in which procedures for building kilns are reported. The craftsman was, for instance, instructed:

When you set up the foundation of a kiln to [make] glass, you [first] search in a favorable month for a propitious day, and [then only] you set up the foundation of the kiln. As soon as you have completely finished [...] no outsider or stranger should [thereafter] enter [the building], an unclean person must not [even] pass in front of [ritual *Kùbu*-images]. You regularly perform libations offerings before them. On the day when you plan to make the *metal* in the kiln, you make a sheep sacrifice before the *Kùbu*-images, you place juniper incense on the censer and [then only] you make a fire in the hearth of the kiln and place the *metal* in the kiln. [20]

3.2 The Greco-Roman World

The use of the term *metal* to designate glass in Assyrian tablets was not accidental. Not only had glassmakers shared many things with metallurgists in their transformations of earthy materials, but fusibility was another reason for considering glass akin to metals, and not to rocks, which could not be melted at the highest temperatures reached in furnaces. Galen (129–216), the most famous physician of Antiquity, defended himself the analogy between glass, gold, silver, and even iron [22]. As a matter of fact, the Greek and Latin terms *metallon* and *metallum* did not refer to any property of the substances but to a common origin in the ground from where they were extracted [23]: in this respect, sand was for glass the analog of ores for the other metals. In this way glass became part of the grand correspondences established in the Greco-Roman world between the seven mobile celestial bodies (the two luminaries and the five known planets) and the seven metals more or less well identified at that time: the Sun was of course associated with gold, the Moon with silver but sometimes with glass, Mars with iron, Venus with tin or copper, and Saturn, Mercury, and Jupiter with copper, tin, electrum (natural Ag–Au alloys), or with glass [23].

In Egypt, their close association with the imitation of precious stones led the glassmakers to be called *makers of lapis lazuli*. It was also in Egypt that glass began its long and tight association with alchemy (Chapter 10.4, [24]). The dramatic transformations clearly undergone by the raw materials in glassmaking raised the issue of the

kinship between man-made and natural materials and sustained the idea that man could even go farther than nature in his own operations (Chapter 10.4).

Such reflections on glasses considered as molten gems were pursued in Greece where elementary constituents or *qualities* were invoked to account for vitrification (Chapter 10.4). But little was said or claimed about real physical properties. When discussing liquids in *On Generation and Corruption*, Aristotle (384–322) emphasized that their “readily adaptable” shape conferred by their “small particles” made their mutual combinations easy, but mentioned “viscous liquids” only to state that they “produce no effect except to increase the bulk,” without alluding to any glass-forming ability [25]. Likewise, Aristotle did not mention at all glass when he adumbrated the notion of viscoelasticity in his *Meteorology*:

A thing is viscous when, being moist or soft, it is tractile. Bodies owe this property to the interlocking of their parts when they are composed like chains, for then they can be drawn out to a great length and contracted again. [26]

The viscous liquids cited by Aristotle were “pitch and birdlime,” not glass, perhaps because of a more fundamental kinship with metals that was briefly evoked by the statement that “Gold, then, and silver and copper and noted tin and lead and glass and many nameless stone are of water: for they are all melted by heat” [26].

A similar theoretical framework was at the basis of Theophrastus’ reflections in his short treatise *On Stones*. To account for the formation of slags (Chapter 7.4) during smelting operations, Theophrastus thus stated that

When silver and copper and iron become fluid, the stone from them becomes fluid at the same time, possibly owing to the moist character of its constituents or possibly indeed through the agency of the metals.

Theophrastus also paid attention to actual glassmaking. Because the kinship of obsidian and man-made glasses was early recognized, of special interest are his remarks about melting experiments made on the well-known obsidian from Lipari island (Southern Italy): “The Lipara stone, which before burning is black, smooth and dense, is not only rendered porous by combustion, but also assumes the appearance of pumice, so that its colour changes along with its density.” Hence, it was obvious that obsidian could not be used in glassmaking. As we now know, the water always present at a few tenths of wt % in obsidian exsolves as bubbles upon heating when the viscosity becomes lower than about 10^9 Pa.s (i.e. at

temperatures of the order of 800 °C) so that, as described by Theophrastus, one obtains a pumice that either quickly devitrifies or is much too viscous anyway to lend itself to any glass-forming operation.

Regarding the fundamental invention of glass blowing made right before the beginning of the Christian era (Chapters 10.3 and 10.5), it will suffice here to recall that the process required a strict control of viscosity during the alternating periods of working and reheating before the final annealing. As for the production of transparent glass that became extensive at the same period, it was relying on the addition of substances now called antimony oxide (Sb_2O_3) and especially manganese oxide (pyrolusite, MnO), the famous *glassmaker's soap* (Chapter 6.2), which had perhaps been an outcome of the making of black glass in Egypt in the fifth century BCE [27]. Thermal shock was another physical process put to use to cut a piece at the desired place and also for severing it from the blowpipe. The dramatic impact of such advances in glassmaking and the practical advantages of glass over metals could have given some credit to the famous legend of malleable glass, shapable with a hammer, told by the Latin writer Petronius (first century CE) in the *Satyricon*: when the emperor was told that no one else than its inventor knew how it was made, he ordered him to be beheaded “because if this invention were generally known we should treat gold like dirt” [28]. If the story has some truth in it, then it might have had as a starting point a parison falling on the ground while being blown and at once recovered by the blower to finish the work [27]. But the fact that Pliny ([19], cf. Chapter 10.0) himself did not take the story seriously has not prevented it from enjoying great success throughout the ages.

3.3 The Western Medieval Literature

In the West, relatively little is known about glassmaking activities after the fall of the Roman Empire. One rare source is the *Etymologies* written in Visigothic Spain by the bishop saint Isidore of Seville (~560–636). Noting that obsidian “is counted as a type of glass. Sometimes it is green and sometimes black, and it is translucent,” Isidore reported that “the highest esteem is granted to clear glass with its close similarity to crystal,” which “used to be made in Italy.” As he explained further,

Throughout Gaul and Spain the softest white sand would be ground with a mortar and pestle, and then mixed with three parts, by weight or measure, of natron, and after being melted it would be poured into another furnace. This lump would be called *ammonitrum*. When heated again, it would become pure, clear glass. [29]

This statement was almost a word by word copy of Pliny's *Natural History* (XXXVI, LXVI, cf. Chapter 10.0), however, so that its actual significance for Isidore's times is unclear. In the Near East, however, it is known that natron production became insufficient in the seventh to ninth centuries possibly from a combination of too high a demand, unfavorable climatic conditions and political turmoil [17] so that *vegetable soda* derived from plant ashes had to be used instead as a flux.

Dating back to the eighth to tenth centuries, some compilations have transmitted recipes dealing with pigments, inks, varnishes, glues, stones, metals, glasses, etc. The best known are the *Compositiones variae* [30], the *De Coloribus et artibus romanorum* transmitted under the name of the seventh-century Byzantine emperor Heraclius (spelled Eraclius [31]), and especially the *Mappae clavicula* [32] whose content and meaningless Latin title today indicate that it originated in Greek alchemical manuscripts from the fourth century [33]. Probably this ancient literature found its way to the West through Latin translations made in Italy in the late eighth century. What is clear is that copyists then kept modifying these compilations by additions and deletions of their own and that quite a few recipes do not make sense technically. Along with correct descriptions of glass polishing or of the red and green colors obtained with copper, the *Mappae clavicula*, for instance, instructed: “Color thin glass pieces, mix and coat them with dragon's blood, and in this way a reddish color will result.” Such technical compilations would be followed by many others: until the fifteenth century, glass recipes are present in more than 120 of them, generally focusing on softening, coloring, and gem counterfeiting [34].

Some compilations incorporated recipes from an Arabic literature that began to be translated in Latin in the twelfth century. From Egypt to Mesopotamia, the ancient glassmaking tradition had become part of the new Islamic world after the Arabic conquests of the seventh and eighth centuries. In Islam, too, marked changes in glass chemical composition took place in the eighth to ninth centuries probably as a result of natron shortage [35]. This was the time when alchemy became extensively practiced and when Jabir ibn Hayyân (eighth to ninth centuries) became a semi-legendary character to whom an immense alchemical literature would be attributed [36]. Although the term *alkali* is the Arabic *al qaliy* (*calcined ashes*) and original processes were devised, new concepts do not seem to have been formulated about glass and its nature. Jabir himself considered it as part of the seven metals and as the best material for making the vessels within which artificial life could be created ([36], cf. Chapter 10.10). Even the great polymath al-Bīrūnī (973–after 1050), who was active in central Asia, devoted more space to poetry than to technical descriptions in the

short section devoted to glass in his celebrated *Book Most Comprehensive in Knowledge on Precious Stones* [37]. His main statement was that glass “is cast from a well-known stone or from sand to which borax has been added. The substance is heated for several days on fire till it accumulates, clarifies and progressively hardens.” That said, al-Bīrūnī simply added that “different colours are imparted to glass while it is being melted. These colours persist.”

From furnaces to processes, the most reliable ancient review of glassmaking is found in the second book of the twelfth-century treatise *On Divers Arts* of the Benedictine monk Theophilus (Chapter 10.9, [38]). Original views on the constitution and properties of glass are unsurprisingly lacking in this work whose goal was to show how God could be glorified by the practice of the most various crafts. Thanks to its technical descriptions and also to the rich medieval Latin terminology it has transmitted, however, this work has been judged to be “one of the three or four outstanding documents in the written history of mediaeval art-technology,” which distinguished itself from the “random conglomerate” of earlier compilations by the way in which it announced “the rational, ordered, unified composition” of fifteenth-century treatises [39].

Another book of the same period deserves a special mention by the original fundamental insights it threw on glass. These were presented in *On the Elements*, a work perhaps written in France toward 1160 by an elusive author named Marius who relied on his own observations to describe how the four elements combined to make up all things from minerals to Man. In his book, Marius was apparently the first author to point out the kinship of glass not with metals, but with ceramics and rocks, and explained in addition how mud was transforming into what we now call metamorphic and igneous rocks under increasingly strong action of subterranean heat. As Marius asked his readers,

Do you also know that the jar of a potter is a kind of glass? But because it was not cooked long, it is therefore not glass. But if it were cooked for a long time by the fire, it would be turned into clear and glittering glass, like the pot of the goldsmith. Now, therefore, you can observe how stones are created in the body of the earth because of insufficient fire; if the fire were greater, the process would be completed and these stones would be turned into glass. Of this sort are the stones we use for the constructions of houses, and marbles of various colors, and the little white stones which are found on the banks of rivers. [40]

And Marius concluded that “there are many kinds of these because of the varieties of earth of which there

are many kinds — I do not mean earth properly speaking — and because of the variation in the amount of heat they receive [40].” But these ideas received little attention as testified by the single extant manuscript of his book, which had to wait until 1976 to be edited and printed.

While miracles would be soon wrought by transparent glass in the form of spectacles (Chapter 10.10), glass was then about to regain in the colored glazing of churches, an importance it had not had since Late Antiquity (Chapter 10.8). Significant innovations (Chapter 10.8) were the production of red glass through complex microstructural effects in the twelfth century and yellow staining with silver salts in the early fourteenth century, followed by the empirical recognition in Venice that purer raw materials were needed to improve quality (Chapter 10.7). Following the use of quartzite pebbles as a source of silica in place of common sand, the complex treatment of soda plant ash made through successive steps of dissolution in boiling water, decantation, filtration, and drying of the final *sale de cristallo* were clearly indicating that a series of well-defined chemical operations was the key to ensure a consistently high quality.

4 The Early Modern Period (Sixteenth to Eighteenth Centuries)

4.1 An Alchemical Backdrop

Glassmaking progress did not affect the old association of glass with alchemy. On the contrary, argued the metallurgist S. Vanoccio Biringuccio (1480–1539) in his *Pyrotechny* (Chapter 10.9), this art was “born from the speculation of good alchemistic savants, through whose efforts it imitates the metals on the one hand and the transparency and splendour of gems on the other.” And although Nature “has produced crystal and all other kinds of gems that are much more beautiful” than glass, Biringuccio added, “no way has yet” been found for working with these as done with glass [41].

The beauty of glass was not necessarily lasting, however, as alchemists had long noticed the degradation of their glass vessels after long exposure to heat and chemicals. The attack of glass by soda and potash was thus described in some detail in several books; for example, in a text attributed to an enigmatic fifteenth-century monk named Basilius Valentinius, probably the pen name of a salt manufacturer named Johann Thölde (1565–1614) who was familiar with chemical processes. Likewise, potassium silicate was produced as *liquor silicum* through reaction of sand with *cream of tartar* (potassium hydrogen tartrate, $C_4H_5KO_6$) by the chemist Johann Rudolf Glauber (1604–1670) after whom sodium sulfate has been named as Glauber’s salt.

This alchemical backdrop would remain clearly present in the reference glass treatises of the seventeenth century (Chapter 10.9). It is, for example, clearly apparent in the *The Art of Glass Making* of Jean Haudicquer de Blancourt (b. ~1650), where one reads: “glass is a perfect metal, since it does not burn more in fire than gold; & that there is only one fire more powerful than that of the common man who can destroy it” [42]. As a reminder of Petronius’ famous story of malleable glass, Haudicquer also mentioned “the Elixir of the Philosophers which makes it malleable, & which converts crystals into very fine precious stones” [42].

But the most dramatic experiments made at the same period were those of the physician and alchemist Jan Baptist van Helmont (1579–1644) who reported that the sand incorporated in glass was actually not dissolved in it because it could be entirely recovered by an appropriate chemical treatment. As van Helmont explained in his *Dawn of Medicine*,

If one melts a fine powder of glass with a large amount of alkali and exposes it in a humid place, one will presently find that all the glass dissolves into a water. If *chrysulca* [mainly nitric acid] is poured on in a quantity sufficient to saturate the alkali, one will at once find that the sand sinks to the bottom [of the vessel] in the same weight as it was before it was used in making the glass. [43]

In fact, van Helmont precipitated alkali nitrates and silica from the aqueous silicate solution. For him, however, the obvious conclusion was that “by means of art, glass returns into its original ingredients once the bond holding them together is broken: the sand can even be regained in the same number and weight” [43]. In other words, van Helmont thought that this experiment with glass had disproved a fundamental tenet of Aristotelian philosophy, namely, the complete homogeneity of mixtures.

4.2 Descartes: The Foundation of a Glass Science

Certainly René Descartes (1596–1650) was not the first observer to be fascinated by the “transmutation of ashes into glass,” as he summarized glassmaking in 1644 in his *Principles of Philosophy*. In this extremely ambitious treatise, his goal was to describe comprehensively the physical world from a few first mechanical principles [44] in the atmosphere of intense intellectual curiosity sustained by the discovery of whole new worlds with the telescope and the microscope (Chapter 10.10). The famous philosopher was also strongly interested in glass in relation to his own optical research that led him to give a theoretical

demonstration of the law of refraction formulated in the early 1620s in the Netherlands (Chapter 10.10). Reflecting on vitrification, Descartes thus explained in his *Principles* that glass,

when still glowing with heat, is fluid because its particles are easily moved [separately from one another] by that force of fire which previously smoothed and bent them. However, when it begins to be cooled, it can take on any figures whatever. And this is common to all bodies which have been liquefied by fire; for while they are still fluid, their particles effortlessly adapt themselves to any figures whatever, and when such bodies subsequently harden with cold, they retain the figures which they last assumed. [44]

At a time when nothing was known about the microscopic constitution of matter, Descartes described in this way not only what we now refer to as the atomic configurations of a material but also the manner in which these vary with temperature. Descartes went on to explain why glass should be annealed because of differential volume contraction on cooling and buildup of what we call internal stress:

glass “is also more fragile when it is cooled quickly than when it is cooled slowly; for its pores are fairly open while it is glowing with heat [...]. However, when glass cools naturally, these pores become narrower. [...] And if the cooling occurs too rapidly, the glass becomes hard before its pores can thus contract: as a result, those globules subsequently always make an effort to separate its particles from one another.” [44]

Although they were heralding the beginnings of glass science, Descartes’ ideas got completely forgotten until the present time [45]. These groundbreaking conceptions probably suffered from the general criticism laid upon the *Principles of Philosophy*. This treatise was judged by many as a “romance” even before the Newtonians rejected his vortices, which played so prominent a role in his wholly mechanical system.

4.3 The Wondrous Lacrymae Batavicae

Descartes’ *Principles* were nonetheless widely read in the seventeenth century. That Newton imitated Descartes by entitling *Principles* his *magnus opum* is clear evidence of the critical interest in Cartesian physics raised in England. Regarding glass, the physicist Robert Hooke (1635–1703) might already have had in mind the *springiness* of the particles implicitly evoked by Descartes when he turned his

Figure 1 Prince Rupert's drops pictured by Hooke; rupture pattern shown on the left [48].

attention to curious glass drops quenched into water (Figure 1, Section 3.0). This early form of *tempered* glass was probably made before 1625 in Mecklenburg, in Northern Germany, and became called either *lacrymae batavicae* (Batavian tears, in Latin) or *Prince Rupert's drops* long after they had been presented by the German-born Prince Rupert of the Rhine (1619–1682) before the Royal Society of London in 1661 [46].

As originally described [47], these glass beads are remarkably resistant to mechanical shock until a final blow or a breakage of their tail makes them explode and shatter as tiny fragments (Figure 1) even when coated of strong glue or cement. To interpret their instability, Hooke first reckoned that “the parts of the glass” take up more room when hot and fluid than cold and hard, but also that quenching “the glowing metal in the Water makes it of a hard, springing, and rarified texture” so that “the sudden flying asunder of the parts proceeds from their springiness.” In the conclusion of this first study of the mechanical properties of glass, Hooke then stated that “a gradual heating and cooling does anneal or reduce the parts of Glass to a texture that is more loose, and easier to be broken, but not so brittle [48].”

5 The Chemical Revolution

5.1 The New Chemical Researches

It had in fact long been acknowledged that there was not a single *earth*, but many such as soda, potash (*pot ash*), lime, or magnesia. Although their constitution remained unknown, they could be distinguished by their differing vitrifiability and solubility in water.

The reputedly best soda was produced in Spain from the ashes of a succulent shrub named *barilla* (*Salsola soda*), which is rich in sodium oxalate, tartrate, and other organic salts that decompose upon combustion after which their ashes combine with atmospheric CO₂. Known as *Alicante soda*, it was far from being pure sodium carbonate with the following average composition: carbonic acid (16.7 wt %), charcoal (15.0%), lime (6.4%), magnesia (2.2%), alumina (2.3%), silica (7.3%), free soda (14.6%), sodium sulfate (4.2%), sodium chloride (2.2%), potash (3.1%), water and other volatiles (26.0%) [49]. A simple way to increase its purity was to take advantage of the fact that, in contrast to their *alkaline* counterparts, *alkali earths* were soluble in water. This purification did not have only advantages; however, as was noticed by the future Saint-Gobain director Pierre Delaunay Deslandes (1726–1803) who reckoned in 1756 that lime then needed to be added to the batch to ensure the quality and workability of the glass [50].

Because of the high cost of imported soda and the need to satisfy an increasing demand for products ranging from soap to glass, the French Academy of sciences unsuccessfully offered in 1775 a price for the production of pure soda from salt. Various attempts were then made before the chemist Nicolas Leblanc (1742–1806) patented in 1792 a process for producing synthetic soda from salt, sulfuric acid, coal, and limestone [51]. As understood only toward the end of the nineteenth century, hydrochloric acid and sodium sulfate (*salt cake*) are first produced by the reaction of salt with sulfuric acid:

The salt cake reacts with coal to reduce the sulfate to sulfide

The sulfide then reacts itself with crushed limestone to yield a mix of soda ash and calcium sulfide termed black ash:

In a final leaching step, the black ash dissolves in water and soda ash is recovered by evaporation of the solution. Because of its elevated cost, the Leblanc process did not meet with an overwhelming success in glassmaking. It was in particular cheaper to follow the simpler procedure established by Gehlen in 1810, which consisted in effecting the Leblanc reactions in the batch itself with about 100 parts of sand, 50 of Glauber's salt, 17–20 of powdered quick-lime, and four of charcoal [2, 3]. But an undesired greenish hue was obtained in this way, which was strongly detrimental to the quality of the expensive plate glass. Chemical analyses performed by Pelouze showed that this hue was originating in slight iron contamination caused

by the reaction with the pots of the excess sulfuric acid present in sodium sulfate, which thus had to be of a high purity [49]. Sodium carbonate – the major chemical produced at that time – nonetheless remained produced with Leblanc's method until the early 1860s when the less-expensive Solvay process was invented (Chapter 1.2). The carbonate then slowly supplanted the sulfate as a sodium source as it was ensuring faster sand digestion and thus shorter melting reactions. Because its major advantages for the fining process had been recognized, however, the sulfate was not completely eliminated. It remains today the main agent used for chemical fining (Chapter 1.3).

5.2 The Discovery of the Elements

Compared with earlier glass treatises, those published from the nineteenth century clearly differ by their numerous tables of chemical compositions. The change was abrupt. In the seventeenth century, as noted by W.E.S. Turner (Chapter 9.12), “there was no realization of the complexity and inconstancy of the glassmaking salt, containing as it did the carbonates of sodium and potassium, calcium and magnesium (these last two in large proportions), of chlorides, sulfates, and phosphates, with silica, alumina, and minor constituents” [52]. Although sodium and potassium salts could at last be differentiated in the mid-eighteenth century, the existence of alkali elements would remain debated until the beginning of the following century when they were at last identified at the same time as the alkaline earths.

Knowing of what the traditionally used salts were made was only a first step toward the modern notions of stoichiometry and chemical composition. Four theoretical concepts derived at the turn of the eighteenth and nineteenth centuries were also needed, namely, (i) the law of definite proportions stated in 1794 by Joseph Proust (1754–1826) according to which chemical elements are present in fixed weight ratios in a given compound; (ii) the first atomic theory formulated by John Dalton (1766–1844) in 1803–1806; (iii) Gay-Lussac's law of combining gas volumes (1808); and (iv) the hypothesis advanced in 1811 by Amedeo Avogadro (1776–1856) that equal number of molecules occupy equal gas volumes.

At the end of the eighteenth century, the new chemical system propounded by Antoine-Laurent de Lavoisier (1743–1794) had opened completely new horizons. As Lavoisier stated himself in his famous *Elements of Chemistry*,

It is likely that we know only some of the metallic substances that exist in nature; all those, for example, that have a greater affinity for oxygen than for carbon, are not prone to be reduced or brought to a

metallic state, & they should present themselves to our eyes in the form of oxides, which we mistake for earths. [53]

In a system that associated a *base* with the new element oxygen in all earths, the problem was to decompose the earths to isolate their bases. In this respect, silica was raising a special difficulty because its remarkable purity in the form of crystal rock could suggest that it was actually a base itself and not an oxide. But attempts at isolating a base from alkali and alkaline earths failed until the invention of the electric pile by Alessandro Volta (1745–1827) and its use in *electro-chemical* analyses of matter.

In his first electrolysis experiments on alkali salts, Humphry Davy (1778–1829) realized that their saturated aqueous solutions were inadequate because water decomposition into oxygen and hydrogen was occurring instead. Made either in air with molten soda in platinum spoon or in glass tubes with wet soda, the experiments were difficult because of the instant combustion of the *bases* of potash and soda in air or of their quick reaction with glass. “Like the *alkahests* imagined by the alchemists,” noted Davy, these bases “acted more or less upon almost every body to which they were exposed” [54]. In spite of the difficulties also met to determine their properties, Davy determined that they were in 86.1 : 13.9 and 80 : 20 weight ratios with oxygen in potash and soda, respectively (actual values: 83 : 17 and 75 : 25). Problems to isolate the bases of the alkaline earths were greater still but those of lime, magnesia, and barite and their properties were nonetheless described shortly afterward [55]. Because the bases of silica and a few other earths did not yield, Davy noted [55]:

Had I been so fortunate to have obtained more certain evidences on this subject, and to have procured the metallic substances I was in search of, I should have proposed for them the names of sili-cium [from the latin *silex*, chert], alu-mium, zirco-nium, and glucium [beryllium].

Going one step farther than Gay-Lussac and Thénard with the same procedure, it was eventually Berzelius who isolated the base of silica, which he found to be in a 48.2 : 51.8 (47 : 53) weight ratio with oxygen, and guessed to be in a 1 : 3 atomic ratio [56].

6 The Crystal Connection

6.1 The Early Glass Ceramics

In the early eighteenth century, much work was done to understand how porcelain was made and, thus, how to imitate at a lower cost the expensive Chinese ware

imported. From his own experimental investigation, the naturalist and physicist René-Antoine Ferchault de Réaumur (1683–1757) understood that porcelain owed its properties to a starting mix of clay such that the material was undergoing partial melting at the high temperatures of the furnaces, which made the product intermediate between terracotta and glass [57]. On the other hand, glassmakers knew well that too much time spent at temperatures appropriate for blowing causes partial transformation of the glass to a whitish material that could no longer be blown. Réaumur figured out that by *devitrification*, one could bring the glass partially back to its initial state and, thus, produce a *glass porcelain* of an admittedly lower quality, but at a much reduced cost. After extensive experimentation, Réaumur found that only some glasses yielded the white material he was looking for [58]. The new product would be called Réaumur's glass porcelain (Figure 2).

In Scotland, the glass–crystal relationship was then considered from a completely different standpoint within a debate that was opposing naturalists about whether water or fire was the main geological agent. When the physician James Hutton (1726–1797) explained that the Earth is a heat engine that gives rise to the great cycles of erosion, sedimentation, petrification, and finally mountain-building, his young friend James Hall (1761–1832) thought that experimental support could be given to these ideas. As a volcanic rock, the iron-rich and SiO₂-poor basalts (Chapter 7.2) were assumed to have attained their present positions “in a state of igneous fusion” [59]. When melted in a glass furnace, however, basalt yielded a glass and not the stony rock observed, which seemed to contradict Hutton's theory. Hall thus thought that during its “slow refrigeration in the bowels of the earth,” the molten mass “had undergone a change similar that of glass into Réaumur's porcelain; and that by crystallization it had lost the vitreous, and assumed the stony character” [59]. Experiments made by Hall on different kinds of lavas in fact showed that a glass was each time obtained upon rapid cooling of the melt, whereas annealing or slow cooling resulted instead in crystallization identical in all respects to that of the original lava [59, 60]. The kinetic nature of vitrification had thus been demonstrated.

These conclusions were soon put to practical use. In France, the chemist Jean-Antoine Chaptal (1756–1832) used basalt as a cheap starting product for the industrial production of bottles in Southern France [61]. After some success, his efforts ended in failure because composition variations of the lava caused melting difficulties and devitrification problems, which did not motivate attempts at solving them because market conditions were favoring clear glass bottles. Molten basalt had thus to wait the very high cooling rates achieved in the production of rock

wool to become of real interest in glassmaking (Chapter 9.3).

6.2 From Melting to Crystallization

Another important advance made at that time was the melting of quartz. With a blowpipe burning an oxygen–hydrogen mix, the Genevan-born British physician Alexander Marcet (1870–1923), a close friend of Berzelius, first vitrified silica in 1813 in the form of small needles [62]. In larger quantities, Marc-Antoine Gaudin (1801–1880) then succeeded in 1839 to draw fibers that were “resembling steel in elasticity and tenacity” [63]. After three and a half millennia of glassmaking, the very high temperatures required for melting silica without a flux had been made possible by the discoveries of oxygen and hydrogen and of their combustion mechanism. According to a seventeenth-century account [64], the Berber poet and astrologer 'Abbas Ibn Firnâs (d. 987) made glass from “stone”. Based on an ambiguous meaning of this term, a common interpretation that he vitrified quartz thus is an unfounded claim.

Flow during the long heat treatments required for the production of Réaumur's porcelain made it difficult to keep the complex shape of the original glass piece. Large plates could in contrast be readily produced, which appeared to be much harder and more resistant to thermal shock than the original glass [65]. These advantages of what we now call *glass ceramics* (Chapters 7.11 and 8.5) were thus already recognized at that time. Regardless of high production costs, what probably prevented applications was rapid alteration in air, for instance, shown by the surface formation of potassium carbonate [50].

Although Réaumur's goal had been to *devitrify* partially glass, the nature of the actual transformation effected long remained debated [50]. Was it simply a physical modification of the glass or the precipitation of crystals of a well-defined composition, which thus differed from that of the glass? Important features supporting the latter interpretation were observed by Théophile-Jules Pelouze (1807–1867) in extensive experiments on Réaumur's porcelains. As summarized by Pelouze, “crystalline nuclei” (i) appear at the glass surface; (ii) grow from both sides toward the interior of the plate; (iii) disappear upon heating at temperatures not higher than those at which the starting glass was melted; (iv) reform upon cooling without any weight change; (v) grow with a kinetics that depends much on composition (for example, fast for sodium trisilicate but vanishingly low for a potassium and calcium borosilicate); and (vi) have a growth rate considerably increased by the introduction of refractory material, sand, ashes, or even batch or glass powders [66]. The difference between what is now termed

Figure 2 Crystal precipitation in a piece of Réaumur's porcelain. Engraving from [50].

homogeneous and *heterogeneous* nucleation was thus also clearly pointed out.

At the end of the nineteenth century, the kinetics of the process was studied in more detail by Gustav Tammann (1861–1938) who established that homogeneous crystallization depends on heat flow and proceeds in two steps, namely, the initial formation of “crystallization centers” followed by growth of the macroscopic crystals [67]. For both nucleation and growth, the rate varies with temperature according to bell-shaped curves (Figure 3), the growth rate vanishing by definition on the high-temperature side at the melting point of the crystal or liquidus temperature. In quenching experiments performed on 153 liquids of many kinds, vitrification was obtained 59 times, which led to the conclusion that most liquids could vitrify, at least in small amounts, if cooled rapidly enough [68]. That the ability of a liquid to supercool depends on the nucleation and growth rates of crystals was in addition for Tammann the “key to the relation between glasses and fusions. A glass is a non-crystalline, strongly supercooled melt” [69], without any definite melting point upon heating to high temperatures.

7 The Multiple Roots of Glass Science

7.1 Composition Innovations

In the seventeenth-century, the production of *flint glass* in England by addition of large amounts of lead oxide to the composition was a forerunner of future changes made in glass composition to yield new, special properties (Chapter 10.10). Because index of refraction scales with density, crystal glass had a distinctly bright and vivid appearance, which instantly met with popular and optical success. Another new family of glass appeared at about the same time in Bohemia. There, potash-lime glass was made from saccharoid limestone, potash-rich

Figure 3 Tammann's depiction of the rates of crystal growth and nucleation with increasing extent of supercooling for a glass-forming liquid whose viscosity increase is also sketched. After [68].

pine-tree ashes, and hyaline quartz as a substitute for rock crystal, which had been extensively mined for the purpose of carving beautiful vessels out of large pieces. The new glass ensured great clarity, even for big pieces, could be ornamented with enamel because it could sustain high temperatures without softening, and for this reason proved to be most valuable for chemical experiments (Chapter 10.10).

Along with flint, Bohemia glass was extensively investigated by the polymath Mikhail Vasilyevich Lomonosov (1711–1765) who wanted to create a glass factory for the production of colored mosaic pieces, beads, pearls, and other fancy or decorative items not made in Russia at that time; before the plant opened in 1753, Lomonosov had already synthesized more than 3000 glasses, which gave him the complete palette of hues he needed to cater to the Imperial court [70]. In practice, this work was restricted to the potash-lime-silica and potash-lead-silica systems to which a host of coloring agents were added [71]. But it suffered from the fact that it was done in the last days of the *phlogiston*-dominated old chemical system and that Lomonosov was perhaps too busy with his numerous scientific endeavors and the management of his glasswork to be interested in glass itself.

In contrast, the discovery of alkali elements and the possibility to analyze them gave a much sounder basis to the study of what came to be called *water glasses* (Chapter 7.5) by the chemist and mineralogist Johann Nepomuk Fuchs (1774–1856) who described new applications such as fire protection for theater curtains [72]. But the compositions of the most common kinds of glasses were not determined at once, as noted in 1830 by Dumas who distinguished soluble, Bohemia, crown, window, plate, bottle, flint, and strass glasses in one of

the first systematic determinations of chemical compositions [73], and got also interested in those of ancient glasses. Since chemical analyses of minerals had clearly shown the existence of stoichiometry relations, Dumas wanted in fact to check the commonly held idea that glasses are “indefinite mixes of various definite silicates”; to his surprise, however, he thought to have found that the very best crown glass was “a definite compound almost as exact as some mineral species.”

Other insights came from investigations of geological materials in which Fuchs participated among many other investigators. Rocks differ widely in the way they react at high temperature. Granite, for instance, is readily melted. From the early nineteenth century, most oxide and sulfide rock-forming minerals were successfully synthesized in the laboratory by mineralogists (e.g. [74]). Efforts were even made at reproducing the texture of rocks. This work involved more than the very few metal oxides that had been used for making glass from the Late Bronze Age. Leaving aside coloring elements, whose concentration is low, these were the oxides of silicon, sodium, calcium, aluminum, potassium, and lead. Boron, in the form of *borax* (actually various hydrates of sodium tetraborate, $\text{Na}_2\text{B}_4\text{O}_7$), and phosphorus from the *microcosmic* salt $[\text{Na}(\text{NH}_4)\text{HPO}_4]$ (Chapter 7.9) were already known at the end of the eighteenth century to be very efficient fluxes, but these rare materials were so costly that their use was restricted to vitrification assays [1].

A few decades later, the vitrifiability issue was re-examined for a variety of elements recently discovered or not. Interest was again paid to phosphorus, from which a glass termed Graham’s salt $[(\text{NaPO}_3)_6]$ had been produced in 1833 (Chapter 7.9). From 1862, the minister William Vernon Harcourt (1789–1871), best known as a founder in 1831 of the British Association for the Advancement of Science, incorporated 14 new elements in 166 different glasses, which he supplied to the physicist George Gabriel Stokes (1819–1903) for optical investigations [75]. Harcourt even discovered the glass-forming ability of B_2O_3 and P_2O_5 , but his efforts had little practical applications before Michael Faraday (1791–1867) realized that addition of boron oxide was a simple means to obtain more homogenous glasses for better optical performance [76].

In Germany, the great optician Ernst Abbe (1840–1905) wondered whether the narrow range of chemical composition of glass was the reason why both refractive index and dispersion (Chapter 6.1) were always increasing in a way similar to density. Was it also the reason why lenses had known little improvement since the invention of flint glass? At Abbe’s instigation, Otto Schott (1851–1935) began in 1881 systematic investigations of the density–optical property relationships of silicate glasses in a work supported by a scientifically oriented

German government. A result was the first commercial production of borosilicate glasses for optical applications. By using all the elements known at that time, Schott could incorporate 28 of them in concentrations higher than 10 wt % [77]. Introduction of barium, a heavy element, for instance, caused an increase of the refractive index of glass without increasing the dispersion. Such observations proved especially useful for microscopy and photography applications. From this work, it became possible to tailor a glass composition for a given specific application as conveniently summarized by the so-called Abbe diagram (Chapter 6.1), in which the range of values that can be obtained has tremendously increased over time (Figure 4).

Further progress in this respect resulted from specific needs. In the United States, a search was, for example, made for glasses with low thermal expansion coefficients because the lights of train cars were breaking under the thermal shock caused by heavy rains. Addition of boron oxide for improving the homogeneity of optical glass already had been described by Faraday [76]. After having also been used by the Schott company to make glass for more stable thermometers, borosilicates resulted in 1908 in the invention of Nonex glass by Corning Glass Works. This lead borosilicate glass was an instant success, but sales soon dropped because the material no longer needed replacement [79]. The use of glass for cooking ware was then considered, but lead-bearing materials were unsuitable for such an application. Further research eventually resulted in 1915 in the famous sodium borosilicate glass dubbed Pyrex, which has extremely small coefficients of thermal expansion ensured by the presence of about 12 wt % B_2O_3 (Chapter 7.6).

Figure 4 The effects of chemical diversification on the refraction and dispersion of oxide glasses as a function of time (after [78]).

The increasing diversity of chemical composition made possible prediction of a given physical property from the composition of the glass. Near room temperature, linear variations of various properties of silicate glasses were observed as a function of the concentration of oxide components (e.g. [80]). Further experimental work revealed deviations from additivity, which were incorporated in more complex models [81]. However, no such effort could be attempted for melts because experimental data would be badly lacking for a very long time.

7.2 The Contribution of Physical Chemistry

It was a cosmological problem that first awakened an interest in the physical properties of melts [82]. According to ideas formulated by Descartes in his *Principles of Philosophy* and then by Leibniz (1646–1716), the Earth had originally been completely melted. Buffon (1707–1788) found support for this thesis in the fact that granite, which was making most of the Earth's crust, could vitrify readily. Buffon was thus led to think that its age could be determined from the time that had been needed to reach its current surface temperature. After him, Joseph Fourier (1768–1830) derived his celebrated heat equation to give a firm mathematical basis to this exercise but appropriate thermal data were lacking to solve it. It was thus to remedy this situation that William Thomson (1804–1907), better known as Lord Kelvin, inspired in England the first measurements of the enthalpy of melting [83] and in the United States of the variation of the melting temperature of a rock with pressure [84].

Geologists were then beginning to determine also the viscosity of magma either from field observations [85] or from direct measurements on molten minerals and rocks [86]. Viscosities also became systematically measured in glassmaking contexts as exemplified by the basic soda-lime silica compositions [87]. From the early nineteenth century, most oxide and sulfide rock-forming minerals had been successfully synthesized in the laboratory by mineralogists (e.g. [74]). But the notion that minerals and their assemblages had well-defined pressure and temperature stability ranges would be lacking until the new science of chemical thermodynamics was established by Josiah Willard Gibbs (1839–1903) [88]. Following Kelvin's impulse, a group of scientists desired to apply Gibbs' principles to the determination of solid–liquid phase-equilibria in oxide systems relevant to geology. They managed to get the support of the steel tycoon Andrew Carnegie (1835–1919) to create in 1905 the Geophysical Laboratory of the Carnegie Institution of Washington where systematic phase equilibria determinations in two-, three-, and multicomponent systems would be pursued during more than half a century by Norman L.

Bowen (1887–1956), George W. Morey (1888–1965), and many other workers [89].

Of particular importance in this respect was the development of platinum-based thermocouples, calibrated via gas thermometry, which made accurate measurements of high temperatures possible [74]. A significant advance was the thermodynamic temperature scale rapidly established up to 1755 °C at the Geophysical Laboratory to which the e.m.f. of Pt–Rh and Cu–Constantan thermoelements were referred [90]. With the quenching method designed to establish phase equilibria for systems in which transformations tend to be extremely sluggish [91], work was first devoted to the phase diagrams of binary systems with Al_2O_3 – SiO_2 [92, 93], of the CaO – Al_2O_3 – SiO_2 ternary [94] and in addition led to the discovery of liquid immiscibility in binary alkaline earth silicates [95]. Such activity was relevant not only to geology, but also to glassmaking either directly or indirectly through the fundamental benefits drawn for the improvements of refractory materials and of optical glasses [96–98].

Of particular importance to metallurgy was also becoming the physical chemistry of silicate liquids because of the role played by the silica-poor slags in blast furnaces in metal processing and refining (Chapter 7.4). It had been realized in the nineteenth century that desulfurization and dephosphorization of the metal could be controlled through exchange reactions with the slag phase. Thanks to the advances already made, it appeared that important insights on these reactions would be gained through their thermodynamic modeling. This is why metallurgists pioneered measurements of the activities of oxides in melts (e.g. [99]) and phase-equilibria calculations (Chapter 5.3, [100]). Particularly in Germany, they also performed extensive measurements of physical properties such as density and viscosity (cf. studies listed in [101, 102]). Likewise, it was with the support of the metallurgical industry that Bockris and coworkers measured the electrical conductivity [103] and viscosity (e.g. [104]) of silicate melts and arrived at the modern picture of partially ionic liquids made up of groups of various sizes.

7.3 Rupture: From Drops to Fibers

Tempered glass long remained a scientific curiosity. The *springiness* of Prince Rupert's drops was consistently assigned to the forced dilation of their interior parts imposed by the quenched surface layers. But controlled HF etching experiments made by Victor de Luynes (1828–1904) showed in 1873 that the extreme strength of a drop is ensured instead by its compressed surface layers whose convergence at the beginning of the tail causes this spot to be the weakest part of the piece

Figure 5 A summary of de Luynes' rupture and HF etching experiments on Prince Rupert drops [104]. Top, left: fracture patterns of drops, the last two sawed horizontally at different places, and drops etched to various degrees without fracture (bubbles becoming apparent). Middle: breakage of quenched fibers. Bottom, rupture of a tempered rod and 1-kg glass piece, and sketch of the HF etching of a drop largely embedded in a plaster plate.

[105]. Upon progressive surface etching, the strength smoothly decreases without any fracturing whereas the lack of any preferred microscopic arrangement within the glass is revealed by the orientation of the conical fracture front toward the particular place of the drop where rupture has been triggered (Figure 5). The unequal "dilation" of the glass layers gives rise to a birefringence also observed under polarized light by de Luynes (cf. Figure III), who concluded that it is the source of the instability that makes the drop explode even under vibrations or temperature changes.

Although tempered glass had long been known, it is unlikely fortuitous that the first process for producing it industrially was patented the following year by François B.A. Royer de la Bastie (1830–1901). His starting point was especially significant because it represented one of the very first applications of glass derived from theoretical considerations. In agreement with de Luynes' ideas, la Bastie thought that the fragility of glass "results from the weakness of the cohesion of its molecules" so that "it may be expected that by forcing the molecules closer together, and rendering the mass more compact, the strength of and solidity of the material should be increased." And since compression is ineffective in this respect, "even when applied to the material in a fluid or soft condition," the solution was to rely on a tempering system "such as is usually applied to steel," which is why la Bastie immersed the hot glass in suitable oil, grease, wax, resin, tar, or pitch [106]. The process

designed in this way for glass sheets did not meet with great success. Reasons were early discussed by the famous engineer Frederick Siemens (see Chapter 10.9), who nonetheless acknowledged that it "caused a great sensation at one time" and induced him to give himself "a great attention to the subject" [107]. Siemens was one of the inventors who patented more efficient tempering procedures, but the technological nature of these advances will not be discussed in this chapter as they are clearly beyond its scope (see Chapter 9.2 instead).

For a material not subjected to extreme stresses, tempered glass may exhibit the most dramatic mode of breakage. In Prince Rupert' drops, the rupture front, for example, moves at velocities measured in the 1450–1900 m/s range [108], such that the ejected glass fragments could break the thick wall of a vessel in which the drop was immersed [109]. But Alan A. Griffith (1893–1963) had not these features in mind when he selected glass to establish his famous theory of rupture, with which the explosive propensity of the drops was at last explained. Griffith was interested instead in the mechanical properties of metals, but he found glass more convenient for demonstrating the considerable lowering of the strength of materials by surface defects [110]. Such practical reasons led him to choose glass fibers for his experiments, which did show a tremendous increase of the breaking stress with decreasing fiber diameter (Figure 6). Because "a fiber consisting of a single line of molecules must possess the theoretical molecular tensile

Figure 6 The marked decrease of breaking stress with increasing fiber diameter (1 MPa = 10 bar). Data of [109] for a glass of unspecified composition.

strength,” in the form of fibers glass had more strength than steel, confirming the aforementioned early conclusions of Gaudin on the strength of silica fibers [63]. But two decades would be needed to put this advantage to practical use for materials reinforcement (Chapter 1.6).

7.4 An Elusive Glass Transition

With the exception of the quenching method, which had to be devised for viscous melts, much of the aforementioned physicochemical research was not specific to glass-forming liquids. The new concepts that would be formulated, and lead to a better understanding of glass–liquid relationships, nonetheless relied on the wealth of such data gathered for oxide and organic glass-forming liquids. The lack of heat effect upon vitrification pointed out by Tammann was in particular not real. The outstanding accuracy of the relative enthalpies in crystalline and glassy forms by Walter P. White (1868–1946) made the detection of calorimetric anomalies possible (Figure 7). In what seems to have been the first mention of the glass transition, White related that

several of the glasses show a decided increase in specific heat at some fairly elevated temperature. No explanation has been established for any of these facts. It seems probable that the increase in specific heat would have appeared in other glasses if they had been carried higher. It may be a phenomenon of considerable importance, but for its complete investigation a knowledge of the expansion and perhaps of other properties of the glasses is desirable. [111]

Figure 7 The calorimetric effect of the glass transition: break in the mean heat capacity curve, $C_m = (H_T - H_{273})/(T - 273)$, of $\text{NaCaAl}_{1.5}\text{Si}_{2.5}\text{O}_8$ observed in drop calorimetry experiments. Data from [110].

As a matter of fact, similarly abrupt variations upon heating of a glass had already been observed for the thermal expansion coefficient [112] or the dielectric constant [113], but these anomalies had then elicited little interest. A few decades later interest in these phenomena was, by contrast, awakening, especially in relation with the annealing of high-quality optical glasses.

Near the empirical annealing range, anomalous endothermic effects were observed in narrow temperature intervals for other silicate glasses [114]. For a variety of silicate glasses [115], an important observation then was that marked increases in both thermal expansion and heat were taking place in the same temperature intervals (Figure 8). But the interpretation of these phenomena was not yet clear since it was concluded that:

The cause of these phenomena may be the melting of some of the constituents of the glass, or the melting of the compound as a whole. Whether or not we conclude that glass melts or starts to melt in the critical region depends mostly on our definition of solid and liquid” [115].

In the same year 1920, Arthur Q. Tool (1877–1967) and C.G. Eichlin [116] observed that the endothermic effects recorded between 450 and 600 °C for different types of

Figure 8 Anomaly of thermal expansion and heat absorption in the same temperature interval upon heating of a light-flint silicate glass. (after [115]).

glasses shift to higher temperatures with faster heating rates and are larger for annealed than for chilled samples (Figure 9). An important conclusion drawn from these results was that annealing “may involve more than the mere removal of stresses” from the glass. But the nature of the other processes involved remained unclear. A possibility was “the formation and dissolution of some

such crystalline structure or other molecular aggregate,” which might also account for the tempering of glass achieved by la Bastie and Siemens without the need of a stress buildup as it was then assumed [116]. Subsequent work by a number of investigators, especially Tool and Eichlin [117], then indicated that a state of equilibrium could be attained through only “molecular rearrangement,” in crystallite-free materials, such that “the density of the glass varies somewhat with the treatment.”

Another approach resulted from the conclusion drawn in 1920 by Gilbert Newton Lewis (1875–1946) and George Ernest Gibson (1884–1959) that, because of the existence of the entropy of mixing,

at the absolute zero there is in general a difference in entropy between a solution and the pure substances of which it is composed. In other words, if we assign zero entropy to the pure substances we cannot take the entropy of the solution as zero [118].

Figure 9 Effect of thermal history on the glass transition of a light flint glass: endothermic peaks recorded in differential thermal analyses. (after [116]).

The existence of a such a residual entropy had a considerable thermodynamic importance with respect to the non-equilibrium nature of glass. It was quickly confirmed by Wietzel who reported that silica glass has at liquid-hydrogen temperatures a higher entropy than crystalline SiO_2 forms [119], but this conclusion was not regarded as definitive in view of the uncertainties affecting the extensive calorimetric measurements needed at high temperatures on which it was relying (Chapter 3.6). Thanks to their low melting temperatures, organic glass-forming systems were lending themselves to firmer statements. From measurements on glycerol $[\text{C}_3\text{H}_5(\text{OH})_3]$, Gibson and William F. Giauque (1895–1982) thus concluded that the excess entropy of 5.6 ± 0.1 cal/mol K found at 70 K for the supercooled liquid over the crystal “will not be appreciably different at the absolute zero” [120].

In these measurements on glycerol, the abrupt 90% heat capacity increase measured for the glass at about 190 K was not commented upon. It was in fact similar to “some remarkable changes” previously observed by Gibson’s team at around 100 °C for ethanol ($\text{C}_2\text{H}_5\text{OH}$) and propanol ($\text{C}_3\text{H}_7\text{OH}$), which had been simply interpreted as “a great increase in the amount of association within the super-cooled liquid” [121].

On the other hand, Alexander A. Lebedev (1893–1969) assumed that glass contained “minute quartz crystals,” forming themselves solid solutions, such that “annealing is not so much the removal of stress as the attaining of complete polymorphic transformation” [122]. His main argument was that the birefringence of optical glass disappears upon annealing near 575 °C, the temperature of the α – β transition of quartz. His views formed the basis for the microcrystalline hypothesis, according to which glass was made up of a disordered arrangement of very small crystals whose structure was similar to that of a stable crystalline form (cf. [123]).

These diverging reflections on the structure of glass were at the roots of the confusion affecting the nature of the physical anomalies observed in glass-forming systems, which apparently White alone had grasped at once as indicating the existence of a new kind of transition. Such divergences notwithstanding, glass formation came to be associated not with any discontinuous change in first-order thermodynamic properties (e.g. volume, enthalpy), but with rapid variations of second-order thermodynamic properties. From their calorimetric measurements on organic substances (Figure 10), George S. Parks (1894–1966) and Huffman eventually recognized the specificity of glass as a distinct state of matter:

While there is no definite temperature, comparable to the melting point of a crystal, at which all properties undergo a sharp change, there is nevertheless a temperature interval, definite and reproducible, in which a number of properties change with a rapidity approaching that observed in the case of the melting process of a crystal. In brief, there is a softening region instead of a melting point. The glass as it exists below the softening region differs so markedly from the liquid existing above that it might well be considered as a different state of the substance. For this reason we have recently suggested the possibility of regarding glass as a fourth state of matter, distinct from both the liquid and crystalline states and yet showing to some extent characteristics of both these states. [124]

Consistent with Descartes’ ideas, a new kind of transition, the glass transition, was at last defined from variations of

Figure 10 Heat capacity changes of organic substances in the glass transition region (after [124]).

Figure 11 Heat capacity hysteresis observed for the glass transition of B_2O_3 ; measurements made upon cooling (1), heating following rapid cooling (2), and heating following slow cooling (3); data from [125].

second-order thermodynamic properties. Whether in organic or inorganic systems, it was characterized by the same heating/cooling phenomenology as checked by Parks’ team with B_2O_3 [125], which could be accurately performed at relatively low temperatures (Figure 11).

Without any reference to polymorphic-like transformations, the very viscous liquid – which was still in internal thermodynamic equilibrium because its state was determined by only two state variables – was separated from the glass by a transition: occurring over a temperature interval of a few tens of degrees, this transition could

nonetheless be characterized by a temperature denoted T_g . The dependence of glass properties on thermal history first observed in 1845 [14, 15] could then be explained simply in terms of the dependence of T_g on the cooling rate (cf. Chapter 3.6) and the subsequent rate dependence of the loss of internal thermodynamic equilibrium.

7.5 Permanent Compaction

Although temperature is the intensive parameter directly relevant to relevant glassmaking operations, the effects of pressure were also investigated by Tammann. In the same way that one could quench glasses with different thermal histories by changing the cooling rate, one could prepare glasses of B_2O_3 , As_2O_3 , $NaPO_3$, phenolphthalein ($C_2H_{14}O_4$), and other systems exhibiting different permanent compaction by varying the pressure from which they were quickly decompressed [126].

Because the liquid is more compressible than the glass, the observed permanent compaction arises from the fact that only the elastic part of compression is released when the glass is eventually decompressed at room temperature to ambient pressure. The density of a glass thus increases with the pressure at which the liquid is quenched. It offers an indirect way to estimate the compressibility of the liquid [127]. Interestingly, glasses compressed at low temperature to pressures of a few GPa also undergo permanent compaction. This effect was discovered by the pioneer of high-pressure physics Percy W. Bridgman (1882–1961) and Simon for SiO_2 glass compressed beyond 10 GPa at room temperature in minute-long experiments [128]. An 18 % compaction was, for example, observed for a peak pressure of 20 GPa. Especially under nonhydrostatic stresses [129], high pressure could thus induce large irreversible configurational changes at temperatures at which the substance is said to be a glass.

7.6 The Relaxation Problem

Whereas a glass is a hybrid phase characterized by a fixed atomic arrangement, like in a crystal, and by the lack of long-range order, like in a liquid, a melt is a phase whose structure changes rapidly in response to variations of temperature, pressure, and other intensive parameters. Because the term configuration designates any microscopic arrangement of matter consistent with a given macroscopic state of the system, in the 1930s, the physicists Franz Simon (1893–1956) and John D. Bernal (1901–1971) termed *configurational* those contributions to physical properties that are associated with structural changes within the liquid [130, 131]. These manifest themselves most clearly as the abrupt variations of the heat capacity, thermal expansion coefficient, and compressibility at the glass transition.

Configurational properties have also a direct bearing on relaxation, i.e. the variation with time of a given property when the structure of the material adjusts to variations of intensive parameters by tending more or less rapidly toward its new equilibrium configuration. To characterize the rate at which a given property, Y , approaches the new equilibrium value, Y_e , the relaxation time, τ_Y , has been defined as:

$$\tau_Y = - (Y_t - Y_e) / (\partial Y / \partial t), \quad (4)$$

where Y_t is the value actually measured at time t . If τ_Y were constant, i.e. not depending on the instantaneous value of Y , relaxation would be described by a simple exponential law

$$(Y_t - Y_e) = (Y_0 - Y_e) \exp(-t/\tau_Y), \quad (5)$$

where Y_0 is the initial Y value. In other words, after a time τ_Y the variation of Y would represent a fraction $1/e$ of the initial difference from the equilibrium value.

An early landmark of relaxation studies was the analysis of the rate at which the strain and birefringence of a glass-forming liquid varies when the internal stresses built on cooling are progressively released upon annealing [132]. This work was of particular importance for optical glass. A noteworthy practical outcome would be standardization of working operations in terms of viscosity for the strain ($10^{13.5}$ Pa s), annealing (10^{12} Pa s), deformation ($10^{10.3}$ Pa s), and softening ($10^{6.6}$ Pa s) points.

Tool and Eichlin [133] noted that these transformations take place at an “effective” temperature, which was later called *fictive* temperature by Tool [134]:

It is inferred that the physicochemical condition or state of a glass is reasonably well known only when both the actual temperature and that other temperature at which the glass would be in equilibrium, if heated very rapidly to it, are known. This latter temperature has been termed the *equilibrium or fictive temperature* of the glass, and a glass is undercooled or superheated according as the fictive temperature is reached by the actual temperature through heating or cooling, respectively.

For viscosity, Lillie [135] showed how equilibrium properties could be measured via reversal experiments made on samples whose fictive temperatures are initially higher and lower than the temperature of interest (Figure 12). A noteworthy conclusion was that relaxation times depend not only on temperature but also on time and initial extent of departure from the equilibrium state (i.e. fictive temperature). Ever since Tool’s pioneering work [134], this is the reason why relaxation models have become complex (Chapter 3.7) whether individual relaxation times are considered intrinsically nonexponential

Figure 12 Structural relaxation in viscosity measurements at 486.7 °C on a window glass (after [135]). Lower curve referring to a newly drawn sample with a fictive temperature higher than the run temperature; upper curve to a sample first annealed at 477.8 °C for 64 hours. Thermodynamic equilibrium reached in about 2000 minutes as indicated by the convergence of these curves.

or relaxation is assumed to be made up of many mechanisms with different relaxation times. In this respect, an important question was to know whether the fictive temperature alone is sufficient to characterize fully the state of a glass at a given temperature and pressure, or if more than one such *order parameter* are needed for accurate modeling of relaxation processes (cf. Chapter 3.7). The right answer is the latter: from kinetic experiments made on a borosilicate crown annealed either at constant heating rates or at constant temperature, Ritland showed that the density, refractive index, approach to equilibrium, and thermal expansion did vary for a same fictive temperature [136].

Phenomenologically, the delayed response characterizing a viscoelastic material (Chapter 3.7) was not new when it began to be investigated as a result of the work done in the nineteenth century on various systems in which the mechanical response lasted after the distorting influence had ceased. According to the *superposition principle* then formulated by Ludwig Boltzmann (1844–1906), the actual response of a material subjected to various excitations can be considered as a linear combination of the individual stress–strain relationships [137]. Regarding viscous deformation, homogeneous glass-forming liquids are such that, as stated by Isaac Newton (1643–1727), “the resistance that arises from the lack of lubricity (the friction) is, other things being equal, proportional to the velocity with which the parts of the fluid are separated from one another” [138]. This proportionality between the stress and strain rate of a *Newtonian fluid* was represented by a dashpot in the mechanical model [139] designed by J. Clerk Maxwell (1831–1879), whose other component was a spring

accounting for the elastic response given by Hooke’s law [140]. This model actually works when relaxation is determined by a single relaxation time for processes whose activation energy is constant. Since these features generally do not hold true for glass-forming liquids, another ancient mathematical device that has proven useful in relaxation studies (Chapter 3.7) is the stretched exponential function, $\exp(-t^\beta)$, which had been introduced by Rudolph Kohlrausch (1809–1858) to describe the discharge of a glass-dielectric capacitor [141]. From a dual practical and theoretical standpoint, an important step was recognition in the mid-1920s that the viscosity of glass-forming liquids does not generally follow Arrhenius laws

$$\eta = \eta_0 \exp (\Delta H_\eta / RT), \quad (6)$$

where $A = \log \eta_0$ is a pre-exponential term and ΔH_η the activation enthalpy for viscous flow (Chapter 4.1). To account for the observed nonlinear variations of $\log \eta$ against reciprocal temperature (Chapter 4.1), Vogel [142], Fulcher [143] and Tammann and Hesse [144] proposed instead equations of the form

$$\log \eta = A + B/(T - T_1), \quad (7)$$

where A , B , and T_1 are constants. This so-called VFT Eq. (7) embodies the fact that viscosity would become infinite at T_1 , which is sometimes called the Vogel temperature. Two decades later, Walter Kauzmann (1916–2009) pointed out that the large difference between the heat capacities of the supercooled and crystalline phases of a substance would cause their entropy differences to vanish at temperatures not much lower than the experimentally observed glass transitions [145]. These *catastrophes* yielding negative entropies of melting and the fact that their temperatures are close to the Vogel temperatures have since then been one of the most fundamental features to be accounted for by theories of the glass transition.

7.7 The Beginnings of Structural Studies

There were two basic prerequisites for the determination of glass structures, namely, the actual existence of atoms and the availability of experimental techniques with which their arrangements could be probed. The microcrystals or molecular rearrangements invoked by Lebedev or Tool were thus speculations relying on fragile evidence as X-ray diffraction studies of the main crystalline silicates had just begun (e.g. [146]). Although the first structural studies were done for glasses from the mid-1920s (e.g. [147, 148]), they were inconclusive because adequate methods were lacking to deal with the experimental X-ray scattering curves of amorphous substances (Chapter 1.2).

This interest then raised by glass structure led the young William H. Zachariasen (1906–1979) to reflect in the early 1930s on some fundamental rules that disordered arrangements should follow. His starting point was that a lack of long-range order was not inconsistent with some short-range order imposed by the bonding requirements of each kind of atom. Another important feature noticed by Zachariasen was the small energy and volume differences between glasses and crystals. With the assumption that the new principles of structural chemistry established for crystals should also apply to glasses, Zachariasen postulated that both types of phases share the same basic structural elements. Because they lack symmetry and periodicity, however, glasses differ from crystals by the fact that disorder begins right at the scale of first-neighbor distances. Regarding the extent of medium-range order, Zachariasen thus stood in complete opposition to Lebedev to state in his famous 1932 paper that

An oxide glass may be formed

1. if the sample contains a high percentage of cations which are surrounded by oxygen tetrahedra or by oxygen triangles;
2. if these tetrahedra or triangles share only corners with each other;
3. and if some oxygen atoms are linked to only two such cations and do not form further bonds with any other cations. [149]

On the experimental side, the situation changed when the method of Fourier analysis was designed to determine radial distribution functions of liquids [150]. In the 1930s, the method was pioneered by Bertram E. Warren (1902–1991) and his coworkers for oxide and silicate glasses (Figure 13). In studies of SiO_2 and B_2O_3 glass, they confirmed Zachariasen's first rule by showing that Si and B are coordinated by four and three oxygens, respectively, and each oxygen by two Si or B [151, 152]. In addition, they coined the expression *random network* to describe the 3-D disordered arrangement described by Zachariasen. Further work on soda-silica glass [153] showed that two different kinds of oxygens must be distinguished depending on whether they are bonded to only one or to two silicons (Figure 14). Together with these notions of *nonbridging* and *bridging* oxygens, respectively, the distinction between network-former and network-modifier cations was another fundamental concept. Warren and Pincus relied on it to discuss liquid immiscibility in binary metal oxide-silica systems in terms of competition of cations for bonding with nonbridging oxygens, whose outcome is determined by the ratio Z/r_c of the electric charges and ionic radii of the cations [154].

Figure 13 The X-ray radial distribution function of SiO_2 glass (after [151]), the first to be determined for silicate glasses. The peak positions yield the distances between first- and second-nearest neighbors, which can be assigned from known ionic radii or interatomic distances in relevant crystals. For well-resolved peaks, the number of neighboring atoms involved can be derived from the peak areas.

Figure 14 Two-dimensional projection of the structure of a soda-silica glass (after [152]). As derived from X-ray data, this random network also accounted structurally for the existence of gradual (instead of abrupt) softening, viscosity decrease upon Na_2O addition (through fragmentation of the silicate network), and electrical conduction (through hopping of the loosely bound Na atoms).

Even before X-ray diffraction was practiced, other methods were used to investigate glass structure. Right after the discovery of the Raman effect in 1928 [155], the spectrum of quartz was recorded by many investigators (e.g. [156]) and its resemblance with those of silica,

Figure 15 Raman spectra of SiO_2 and B_2O_3 glasses (after [158]). Sharp peak at 808 cm^{-1} in the spectrum of B_2O_3 now assigned to boroxol rings (7.6).

crown, and flint glasses pointed out [157]. Although the Raman signal excited by mercury lamps was weak, the early spectra, for example, recorded for SiO_2 and B_2O_3 glasses compare remarkably well with modern results (Figure 15). For the variety of silicate glasses studied, characteristic features could be assigned to specific structural units present in the structure; although the need for more systematic measurements was pointed out to make reliable specific band assignments, substitution of Al for Si, for instance, indicated a lack of marked structural changes whereas, in agreement with the ideas of Zachariasen and Warren, bands below 550 cm^{-1} were attributed to lattice modes [158, 159].

Instead of the parameter Z/r_c used by Warren and PinCUS [154], Adolf Dietzel (1902–1993) introduced in 1942 the notion of field strength, $I = Z/a^2$, where a is the distance between ions (metal cation and oxygen, in general), to rationalize the systematic variations of devitrification tendency, compound formation, and melting temperatures observed as a function of the nature of cations [160]. That there exists a strong correlation between physical properties and the degree of polymerization of the structure was recognized by Stevels [161, 162] who defined a parameter X to designate the average number of nonbridging oxygens per tetrahedrally coordinated cation; this is of course what is now explicitly denoted by NBO/T (Chapter 2.4). In another approach, the structure–composition relationship was interpreted instead in terms of *structons*, i.e. a limited number of entities made up of a given atom and its nearest neighbors, which changed abruptly with composition [163].

Ironically, the structural heterogeneity claimed by the microcrystalline school bore some analogy with van Helmont's ancient ideas and the strongest evidence for it (see [122]) was in fact the result of metastable liquid–liquid phase separation, which was discovered only in the early 1960s (see [164]). Although random network models are probably too extreme in denying significant medium-range order, the issue of crystalline-like ordering has been raised again recently [165]. Nonetheless, Zachariasen's rules still represent a useful starting point for discussions

of glass structure (Chapter 2.1), which remain themselves common starting points for structural investigations of liquids [166].

8 Perspectives

An interesting contrast is to be noted between chemistry treatises of the eighteenth century and those of the late nineteenth century. Glass was an important topic in the former, in particular because of the basic distinction that was then made between the *vitrifiable* earths and the others (e.g. [5, 167]). In the latter treatises, glass was in contrast paid little attention possibly because the identification of alkali, alkaline earth, and other elements had made the vitrifiability criterion operationally useless in chemistry and perhaps also because glass was no longer thought to raise new important problems by itself. Representative in this respect were the big physical chemistry treatises of Jacobus Henricus van't Hoff (1852–1910) [168], Wilhelm Ostwald (1853–1932) [169], Walther Nernst (1864–1941) [170], or other authorities. In a short section, Nernst, for instance, contented himself to endorse Tammann's ideas about glasses as supercooled liquids by stating that, externally, glass

has the properties of a solid, owing to great viscosity and considerable rigidity, produced by strong mutual action of the molecules. An amorphous body differs from a crystal, however, in its complete isotropy and absence of a melting point; on heating, it passes continuously from the amorphous to the usual liquid state, as its properties show steady change with rise of temperature, and no breaks anywhere. [170]

Ironically, the glass transition was about to be discovered whereas a long chain of studies had already given rise to the glass electrode [171], which would have so much impact on chemistry (Chapter 5.8). It is in fact a recurring theme in history of science that breakthroughs are made

right after important problems seemed to be settled for good.

Building on a long century of advances made in physics and chemistry, a specific glass science crystallized, so to speak, in the critical decade of the 1920s by bringing together physical, chemical, dynamical, and structural features. Of particular importance was then organic substances, which were much more amenable to precise measurements than inorganic glasses. For oxide glasses, this new science was early reviewed in books by Tammann [172] and Morey [173]. Comparison of their contents with that of the *Encyclopedia* illustrates the course followed since then from both experimental and theoretical standpoints.

Like SiO_2 , some “ancient” glasses are now made in completely new ways for completely new applications such as optical fibers (Chapter 6.4) or aerogels (Chapter 8.3). For other applications, wholly original glass compositions have in contrast been designed as illustrated by chalcogenide and fluoride systems (Chapters 6.5 and 6.6). As for organic polymers (Chapters 8.7 and 8.8), they have given rise to major industries because of the ubiquitous uses they have found.

Also noteworthy are the newer fields of metallic (Chapter 7.10) and bioactive (Chapter 8.4) glasses with their serendipitous beginnings and their variety of applications. The former were first produced when Pol Duwez (1907–1984) was attempting to quench metastable crystalline solutions by ultra-fast cooling [174]. They were then engineered as advised by the old glassmaker adage according to which “fusibility is the greatest when the number of bases is the largest” [50], which was previously applied to the so-called “invert” glasses [175]. Although these materials are SiO_2 -poor, they bear a number of other oxides so that they vitrify because their configurational entropy is maximized and both their liquidus and crystal nucleation rates are minimized.

Regarding bioactive glasses, the first one was synthesized by Larry Hench (1938–2015) following a chance conversation in 1967 with a US army colonel who was looking after badly injured Vietnam veterans, and challenged him to produce a material that would not be rejected by the human body [176]. Hench’s first choice was a P_2O_5 -bearing SiO_2 -poor soda-lime silicate composition, which he was expecting to form *in vivo* a hydroxyapatite layer matching well bone tissue. This glass did work well, not as the expected stable material but, rather, as a source of elements for natural regeneration in a way analogous to that of water glass in industrial processes (Chapter 7.5), raising along the way fascinating problems at the frontier between the inorganic and biological worlds.

Of course, it is by definition difficult to guess what additional domains will develop and give rise to new problems

in glass science. In this respect, the fields of ultra-stable and hybrid glasses (Chapter 8.9) have already reached more than a critical size, but there is little doubt that others will keep emerging. From a theoretical standpoint, major challenges remain to be overcome before glass science can be considered fully mature. If one uses structure as a probe of the energetics and dynamics of glass-forming systems, then average structural parameters such as NBO/T are, for example, no real substitutes for the actual distributions of the relevant parameters whose physical significance should be ascertained and variations with temperature and pressure be determined to understand the still elusive nature of configurational changes.

On another basic level, the ever-increasing compositional diversity of glasses makes the yet unsolved problem of the glass transition still more acute as it transcends any features particular to given classes of materials. “The glass transition is not well understood,” already noted in 1972 Angell and Rao [177] who added that “outside the circle of specialists in the area it is not usually even recognized that changes in thermodynamic properties are associated with vitrification.” If the latter statement is now probably no longer valid, the important issue is to know how many more decades will be needed to solve the former problem.

10.12

Glass Museums

Dedo von Kerssenbrock-Krosigk

Glasmuseum Hentrich, Düsseldorf, Germany

1 Introduction

“A museum is a non-profit, permanent institution in the service of society and its development, open to the public, which acquires, conserves, researches, communicates and exhibits the tangible and intangible heritage of humanity and its environment for the purposes of education, study and enjoyment” [1]. This definition was worked out by the International Council of Museums (ICOM) during its 22nd General Assembly in 2007. It is not fixed, but has evolved “in line with developments in society” and is thus updated by ICOM “in accordance with the realities of the global museum community.” There are few limitations as to what a museum might be, ranging from memorials to places of fun and entertainment. With about 55 000 of them worldwide (and more than 280 in London alone), it seems indeed that we live in an age of museums, where everything one can think of is being collected, conserved, researched, and exhibited.

Such activities can be traced as far back as ancient Mesopotamia: a collection of even then ancient artifacts had been accumulated by Nabonidus (r. 556–539 BCE), the last king of the Neo-Babylonian Empire. It was apparently partly labeled, and stored in a palace that probably served as the residence of his daughter Ennigaldi-Nanna [2]. Whereas it is certainly too far fetched to call this palace a museum (and Ennigaldi the first curator in the history of mankind), as some Internet publications would have it, the idea of assigning value to certain objects and to make them stand out – because of their material, of their role as an idol, as a work of art, as a political statement, or because of other conceivable significances – seems to

be very old. Among the earliest precursors of museums were the treasure houses, of which only the Shōsōin in Nara, Japan, may be mentioned as it has survived for more than 1200 years and still exists: It is mainly composed of the belongings of the emperor Shomu, which his widow Komyo donated to the Todaiji temple in Nara in 756 CE. In 950, further objects were moved to the treasure house. The Shosoin was sealed and kept under the supervision of the Imperial court until the nineteenth century, its contents having been preserved in an outstandingly perfect condition [3].

An important step toward the modern museum was taken when the *Kunst- und Wunderkammer* (Cabinet of art and wonders, in English, or *Cabinet de curiosités*, in French) emerged in the late fifteenth century. It developed in the context of a renewed curiosity in nature and its artificial imitation [4]. These cabinets ideally presented a collection from all spheres of both the natural and the artificial world, and displayed a scientific interest in systematically collecting and studying artifacts. *Kunst- und Wunderkammern* were situated within palaces, and could be spread across a series of rooms, but could also be limited to a single wooden cabinet (*Kunstschränk*). The display of curiosities, treasures, and above all, paintings, became a dominant feature of palaces in the course of the following centuries, and at the beginning of the eighteenth century, palaces began to be enlarged by separate wings dedicated exclusively to the art collections, such as in Salzdahlum (1700) and in Düsseldorf (1712) [5]. At the same time, science museums emerged, such as the Ashmolean that was founded in 1683 as a center for the sciences in Oxford, and only later turned into a museum of art and archeology [6]. In 1759, The British Museum opened its doors to the public as the first national public museum in the world, having been founded six years before with the bequest of the collector Sir Hans Sloane (1660–1753).

Reviewers: R. Liefkes, Ceramics and Glass, Victoria and Albert Museum, London, UK

Teresa Medici, Universidade Nova a Caparica, Caparica, Portugal

In 1792, the “Musée Français” was established in the Louvre palace. It was a manifest expression of making the private royal treasures the property of the people in the course of the French revolution. The royal palace was turned into a space for the democratic public, and the museum became heir of its former purpose, representing in particular the nation’s glory by demonstrating its past and its conquests, as it were, of art from former great civilizations.

The truly great era of museums started in the nineteenth century, when ancient art in particular was seen as an important model for taste and morale. In the course of industrialization, of World Fairs, and of the competition between nations in encouraging and developing the domestic arts and crafts, museums became a vital instrument of educating the public, and especially the craftsmen and artists [7]. National museums and museums of applied arts were founded in great numbers, such as the Germanisches Nationalmuseum, Nuremberg, and the Victoria and Albert Museum in London, both in 1852, and the Nationalmuseum, Munich in 1855. Their original missions were either to celebrate the nation and its historical products, or – specifically for the museums of applied arts – to encourage the arts by informing and educating craftsmen and artists as well as customers with historical examples and patterns of ornaments and shapes. These missions have shifted substantially over time, but the original concepts continue to shape our general understanding of these institutions as places of collecting, preserving, researching, and communicating our heritage.

2 The Invention of the Glass Museum

When glass started to be produced in the ancient Middle East, in about 1500 BCE, it seems to have immediately been considered a precious material that was worth to be kept as a treasure (Chapter 10.2). Early glass survived in perfect conditions in the tombs of the Pharaohs of the New Kingdom, from the sixteenth to eleventh centuries BCE, which were furnished with glass vessels, inlays, and sculpture of exceptional quality. The Shōsōin, the abovementioned treasure house in Nara, Japan, houses to this day a number of glass vessels dating from the fourth to sixth centuries CE that must have traveled on the Silk Road from the Middle East to Japan [8]. Rarity and distant origin of production may also have been at the core of introducing Byzantine and Near Eastern glass objects into Western medieval church treasures. Glass occupies a place of pride in the treasury of San Marco, Venice [9].

In 1713–1714, King Frederik IV of Denmark had a room in his castle Rosenborg in Copenhagen turned from

a gallery of small paintings into a glass cabinet. To this day, the room houses a glass collection that Frederick had been given by the city of Venice during his visit in 1709 [10]. The collection is of utmost value as a time capsule, a window into a very specific and interesting period of glass production. Venice, or more precisely, Murano, was the world capital of glassmaking at the time (Chapter 10.7), but the pressure from competition with Central Europe and England was mounting. Moreover, the Rosenborg glass cabinet is perhaps the first instance of an entire room being dedicated exclusively to glass. It was displayed following the example of porcelain cabinets that emerged in the Netherlands and became fashionable in Central Europe (beginning with Oranienburg castle in Brandenburg) in the 1660s.

Apart from Rosenborg castle, there have been other prominent displays of glass at the time, such as the Green Vault, established in 1723–1730 in the city palace of Augustus the Strong in Dresden, Saxony, which features an impressive number of gold ruby glass vessels. Yet, such a focus on glass as in the Rosenborg cabinet is not known to have existed anywhere else until the nineteenth century. Both the Rosenborg cabinet and the Green Vault originally formed part of treasuries, and thus were not open to the general public (today, both are very popular museum attractions). And yet, it may be fairly acceptable to call the Rosenborg glass cabinet the first glass museum of the world.

Treasuries have been among the predecessors of some of today’s glass collections. But the emergence of public glass displays within arts and crafts collections, as well as archeological museums, is even more significant. Most of the best public glass collections today have not been turned into autonomous glass museums, but continue to be a part of larger museum entities, such as The British Museum and the V&A in London, The Metropolitan Museum of Art in New York, the Museum of Applied Arts in Prague, the Römisch-Germanisches Museum in Cologne, and so forth. Even the Glasmuseum Hentrich, which bears the title “museum” in its name, is in fact a department of the Kunstpalast in Düsseldorf. If this chapter were limited to glass museums in the strictest sense, all of these collections and many more would have to be excluded. Instead, if only for the purpose of this overview, a “glass museum” shall be defined as any public glass collection whether as a glass museum on its own, or embedded in a larger museum entity; in short, this essay will consider both glass museums and glass collections in museums. “Glass museum,” “glass collection,” and “museal glass collection” will be used more or less synonymously, for the mere purpose of avoiding too much redundancy.

Before delving into the details of glass collections, it should be noted that some museums (or public galleries)

do host noteworthy glass exhibitions without building up a permanent collection of their own. Among the examples are the National Glass Centre in Sunderland (Tyne and Wear, England), as well as the Reiss-Engelhorn Museums in Mannheim (Germany), which cooperate with the Design Museum (mudac) in Lausanne (Switzerland) [11, 12].

3 Glass Museums

It is not within the scope of this chapter to provide a list of all existing glass museums. Each of the nine numbers of the *Bulletin des Journées Internationales du Verre*, published between 1962 and 1983, provides information on the glass collections of one specific country [13]. An *International Repertory of Glass Museums and Glass Collections* has been published in 1966 [14]. The initiative for this repertory came from the Comité international pour les Musées et collections du Verre (today: ICOM Glass), a chapter, established in 1959, of the ICOM. A list of glass collections on the website of ICOM Glass is currently being put together [15]. Such a list is already online for glass collections in Germany, hosted by the website of the Deutsche Glastechnische Gesellschaft [16], and a number of Italian glass museums have been listed on the website of the Italian committee of the AIHV [17]. A list of glass museums in the United States has been compiled and updated since 2008 at the Rakow Research Library of The Corning Museum of Glass and is available there upon request [18]. A brief overview of French glass in museums in France and abroad has been given by Daniel Alcouffe [19, 20]. Similar accounts exist for English [21] and Scottish [22] glass, respectively, as well as for glass museums in the Czech Republic and in Slovakia [23]. There is also, albeit in Japanese, a directory of glass museums, shops, galleries, and studios in Japan [24]. Last but not least, the publications of Helena Horn [25] and Shaun Kiddell [26] should be mentioned in this context.

Depending on their respective roots, their environment, and their mission, glass museums take on quite a variety of roles and characters. The following attempt at a classification may merely serve to understand better just how varied the field of glass collections actually is.

4 Types of Glass Collections

4.1 Princely Collections

No palace of the higher aristocracy in Europe can be imagined without glass – windows, chandeliers, and mirrors were significant features of any of them, and those of pristine quality were more challenging to make than drinking

vessels. Versailles and its *Galerie des Glaces* need to be mentioned here, as well as the palaces of the Stiftung preußische Schlösser und Gärten Berlin-Brandenburg. With its interior mostly unchanged since 1770, Eggenberg castle near Graz, Austria, offers the unique opportunity of experiencing on special occasions the original baroque candle light from glass chandeliers and candelabra [27].

In some cases, a particular king or prince took a particular interest in glass, which resulted in collections such as in Castle Rosenberg and the Dresden Green Vault – already mentioned – or in the Veste Coburg. The glass collection of duke Alfred of Sachse-Coburg-Gotha (1844–1900) has been documented particularly well. There seems to have been a special affinity for glass among members of that family, as the collections of the Palacio da Pena and the Museu de Arte Antiga in Lisbon demonstrate. These ties, and the interest and practice in nineteenth-century glass collecting in principle, are currently being researched extensively [28].

4.2 Museums of Decorative Arts Versus Museums of Cultural History

The Museum of Manufacture, then South Kensington Museum, and today Victoria and Albert Museum was founded in 1852. It followed in principle the structure of the London World Fair of 1851 in that it arranged its collection according to the respective industries ([7], pp. 36–38 and 99–100). This system proved to be a lasting concept that has been followed by many other museums, such as the Austrian Museum for Art and Industry in Vienna (today “MAK”). From the onset, glass formed a class of its own in these museums. It was separated from stained glass, though, thus reflecting the difference in the production of glass vessels from the making of leaded windows. That separation can be felt in glass collections to this day, which – apart from the very few specialized stained glass museums – tend to focus almost entirely on glass vessels and sculpture. The V&A has largely maintained its original concept in that glass is exhibited in a space of its own, if regrettably too small a space to do justice to the size and superb quality of its collection. Some of the best objects are shown alongside other materials in thematically arranged galleries of the museum.

Thematical galleries – period rooms, or other displays of art of one time period – are also an inheritance of nineteenth-century museum concepts, and aimed at the education of a general public in their cultural history. A good example is the Bayerisches Nationalmuseum (Bavarian National Museum) in Munich. It was founded in 1855, and its mission was quite simply to keep the arts and crafts of the past from sinking into oblivion. The collections, consisting mainly of the possessions of the House of Wittelsbach, were organized by Jakob-Heinrich von

Hefner-Alteneck (1811–1903), their director from 1868 to 1886. Hefner realized that galleries arranged according to aspects of cultural history (essentially, period rooms) could display but a tiny fraction of the large collections. He therefore installed “special collections,” which he organized, following the model of museums of applied arts, according to the respective industries [7, p. 126].

Today, just looking at the permanent displays, it may be hard for a visitor to discern whether the respective museum has its roots in an educational facility for the applied arts, or if it originated as an institution of cultural history. The lines have been blurred from the onset. Especially since the 1870s, decorative arts collections were included into museums of art, history, and culture, and vice versa, museums of applied arts began to look for new concepts of display. The Deutsches Gewerbe-Museum in Berlin (today the Kunstgewerbemuseum, Staatliche Museen zu Berlin Preußischer Kulturbesitz), which opened in 1868, had a section on vessels sorted first according to their epochs (Ancient, Middle Ages and Renaissance, Modern) and only then by material. The Metropolitan Museum of Art in New York was founded in 1870 “for the purpose ... of encouraging and developing the study of the fine arts, and the application of arts to manufacture and practical life, of advancing the general knowledge of kindred subjects, and, to that end, of furnishing popular instruction” [29]. In its setup, the museum separates the decorative arts from paintings and sculpture and arranges them according to their periods of style – some spectacular, original period rooms included.

The history and original purpose of a museum not only have an impact on the display of its collections but also guide the specific goals of collecting specimen of various materials. Shapes and ornaments that could serve as models for artists and craftsmen were the focus of the museums of applied arts; objects that typify a certain period and show, beyond their artistic quality, some interesting cultural or historical aspects were sought after by museums of cultural history. If installing a period room, a museum keeper might look out for mirrors and lighting fixtures in particular. Both are remarkably absent, certainly in terms of permanent display, from those collections that tended to separate their holdings by material.

That the intricacies of a collection are shaped by changing interests over the course of time can be demonstrated by the Glasmuseum Hentrich in Düsseldorf, Germany [30, 31] (Figure 1). Its roots go back to the Düsseldorf museum of decorative arts that was opened in 1883. It was geared toward the local and regional craft workshops and industries by providing examples of good artistic craftsmanship (“Vorbilder” and “Muster”), both in the form of real objects and of a library of photographic images. For various reasons, the privately funded

Figure 1 Kunstpalast, Glasmuseum Hentrich. Details of its bright-red “treasure house” of 2006, providing a chronological path through the history of glass on three levels. Source: Photo: LVR-Zentrum für Medien und Bildung, Stefan Arendt.

museum had to close in 1927, and the lions share of its collection was transferred to the newly opened, local Art Museum. The prominent and somewhat disrespectful display of the accession numbers on the objects is characteristic for their use as models. The shape of an enameled beaker (Figure 2) might, for instance, have appealed to a producer of beer glasses, while the decoration could have served as a formidable example of German Renaissance blazonry. This particular glass has not been kept for being outstanding. It is an ordinary, typical, and perfectly sound example of its kind, and the visible number allowed for quick identification and reference.

In the new context of the “Kunstmuseum,” the utilitarian aspect of demonstrating objects such as these to craftsmen completely vanished. Initially, the Kunstmuseum had no use for these collections at all, as it had been conceived as a museum of fine arts. For the next five years, the decorative arts may well have been stored away

Figure 2 Large beaker (“Humpen”), dated 1603, with coats of arms, and prominent display of its museum inventory number. Bavarian Forest, late nineteenth century (before 1887). Kunstpalast, Glasmuseum Hentrich (11275). Source: Photo: LVR-Zentrum für Medien und Bildung, Stefan Arendt.

completely, but they received renewed attention after 1933, at the beginning of the National-Socialist era. While the collection of modern art was to suffer heavy losses because of the Nazi’s aversion against modernism, interest in the decorative arts was growing, and the “importance of the objects” recognized “as expressions of cultural life” [32]. Between 1935 and 1948, three significant glass collections (Lückger of Roman and Medieval glass; Jantzen of European glass, mainly German Baroque and Biedermeier) were purchased, while a fourth attempt at a purchase (collection Eigel) failed. Not only glass was being acquired, but also ceramics, perhaps because both materials were comparatively affordable and allowed to focus on the regional, German art production, e.g. Roman glass from Cologne, Renaissance-forest and enameled glass, and engraved goblets of the Baroque period. The growth of the glass collection may also have been a reflection of Düsseldorf’s international reputation as a center

for glass technology. Until 2005 it was home to the largest glass bottle factory in the world, Gerresheimer Glas, as well as to the German trade association for packaging glass (Fachverband Behälterglasindustrie e.V.), and it continues to host Glasstec, the largest glass industrial fair in the world.

The wave of glass acquisitions in Düsseldorf almost coincided with the respective augmentation of the V&A’s collections: English glass from Mr. and Mrs. C. Rees-Price in 1925, followed by the collection of Francis Buckley, and, in 1936, the donation of Wilfred Buckley’s collection of European glass. Other than the V&A, however, which aimed for an even growth in all of its departments, in Düsseldorf there was a clear focus on glass and ceramics. Today’s quality of the Glasmuseum Hentrich is mainly due to the donations given by the architect Helmut Hentrich in annual installments from 1961 until his death in 2001. Already in the 1970s, his gifts outnumbered the rest of the collection so that in 1995 the glass department adopted his name. From a small number of glass objects within a museum of decorative arts to a collection of glass as an expression of German culture, and more recently to a collection of international glass art, the Düsseldorf glass collection has undergone significant changes, which are all reflected in its present appearance.

Turning a miscellaneous museum collection that includes some glass into a more or less autonomous glass museum seems to be a phenomenon of the twentieth century based on private initiative. This has not only been the case at the Glasmuseum Hentrich, but also at two other institutions that can rightfully be counted among the largest and most varied glass museums in Europe: the Museum of Decorative Arts in Prague and the Grand Curtius in Liège.

The history of glass in Bohemia goes back to the Middle Ages, and the glass industry and trade became a major commercial factor for the region since the early eighteenth century. It therefore does not come as a surprise that glass is the main focus of the Museum of Decorative Arts (Uměleckoprůmyslové museum, or UPM) in Prague. The museum had been founded in 1885 by the Prague Chamber of Trade and Commerce, and received in 1906 the famous glass collection of Adalbert von Lanna (d. 1909) as a donation, followed in 1932 by the bequest of the glass collection of the museum director and scholar Gustav E. Pazaurek (d. 1935). These donations allowed the museum to become the Czech national glass collection, as it were, assisted by the various regional glass collections in Jablonec (specialized on glass jewelry), Nový Bor and Kamenický Šenov (glass heritage of Northern Bohemia), Sazava and Karlovy Vary (see Section 4.5), Klatovy (glass in Southern Bohemia, especially Loetz), as well as in Brno, Liberec, Pardubice, and Železný Brod (M. Hlaves, private communication).

The glass department at the Grand Curtius in Liège, Belgium, plays a special role among glass museums in that it has been the cradle of the two main international research societies in the field of the history of glass. Joseph Philippe (b. 1919), then director of the Curtius museum, had founded the “Journées Internationales du Verre” in 1956 and hosted the first gathering during an ICOM congress two years later. From this initiative, ICOM Glass was formed in 1959 (mentioned above), and the body founded by J. Philippe was renamed in 1967 *Association Internationale pour l'Histoire du Verre* (AIHV, *International Association for the History of Glass* [33]. The foundation for the Liège glass collection was established by the collector Alfred Baar (d. 1907) and his son Armand (d. 1942). Their collection amounted to more than 2400 items, which were given as a loan to the Musée Curtius in 1946, and were purchased in 1952. For many decades since 1959, the glass collection acted as an independent “musée du verre,” but it was reintegrated into the completely refurbished Grand Curtius in 2009. The glass collection has its particular strengths in the field of glass *à la façon de Venise* (Chapter 10.7) which played a significant role in the seventeenth-century Southern Netherlands, and of products of Val Saint-Lambert, at times one of the world's largest glass factories.

A number of museums of decorative arts need to be mentioned here. In the 1970/80s, the directors of the Kunstgewerbemuseum in Berlin, the Museum für Angewandte Kunst in Cologne, and the Museum für Kunst und Gewerbe in Hamburg – Franz Adrian Dreier, Brigitte Klesse, and Axel von Saldern – were all specialists in the history of glass, and thus contributed to the growth, character, and research of their respective collections. The museums of decorative arts in Bremen, Frankfurt, and Kassel host significant glass collections. The Musée des Arts Décoratifs in Paris comprises the most important general collection of glass in France.

4.3 Archeological Collections

Almost all of the abovementioned museums include archeological collections, i.e. excavated artifacts mostly from Antiquity and the Middle Ages (today, archeology can extend into the twentieth century). A clear distinction should be made, however, between museums that acquired archeological artifacts from private collections or in the art market, and those museums that act as the repository for official excavations. With rare exceptions, the possessions of the first group lack proper documentation: it can often not be excluded that they surfaced by illegal diggings, and the original location and context of the finds is either completely lost, or passed on with little reliability.

Very few “official” archeological museums would consider calling themselves a glass museum. One exception is the Museum of Ancient Glass (Muzej antičkog stakla, or mas) that opened in Zadar, Croatia, in 2009. It is dedicated exclusively to archeological glass finds, mainly from the Zadar Roman necropolis and other regional excavations [34]. Archeological collections tend to be of highest importance for our knowledge about the history of glass. Artifacts in these collections usually have a firm date and origin (at least in terms of their use), and can often be tied into a social or cultural context. Related finds may show whether an object has been a rare treasure or a common item of daily life; and comparisons with other archeological collections give clues as to how far certain objects have traveled. Institutions that are responsible for the archeological heritage of a region (not always museums, but also regional offices of ground monument conservation) are not selective, but keep, in principle, every artifact that falls into their realm.

The majority of these finds are rarely exhibited, and glass tends to form but a minor part of the various holdings. Nevertheless, almost every archeological museum owns some glass (provided, of course, that this material had been known to the region that the museum is representing). Significant artifacts of Roman glass (Chapter 10.3), to give an example, can be expected to exist in practically every archeological museum in Italy, and beyond in the former territories of the Roman Empire. The Museo nazionale Archeologico in Naples stands out for its collections of glass from Pompeii and Herculaneum. Roman glass of superb quality is also shown at the Römisch-Germanisches Museum in Cologne or the Römisch-Germanisches Zentralmuseum in Mainz. The Pokrajinski Museum in Celje (Slovenia), founded in 1882, is dedicated to the excavations of the Roman necropolis of Celeia. Only two examples for post-Roman archeological glass collections may be given: among the most prominent collections of the Regional Museum of the city of Biograd na Moru (Croatia) are the finds, glass in particular, from the sixteenth-century Venetian shipwreck that sunk in the Adria near Gnalić. Excavated glass vessels from the Roman period into the eighteenth century are part of the collection and on view at the Museum of London, which is an amalgam of the former Guildhall Museum, an archeological collection founded in 1826, and The London Museum of 1912.

4.4 Scientific and Technical Collections

Scientific collections were among the first to include glass. The Museo Galileo in Florence, Italy, is particularly noteworthy, as it houses a truly special collection that goes back to the seventeenth-century Accademia del Cimento. The collection was rediscovered in 1839 by

the director of the Museum of Physics and Natural History, one of the predecessors of the Museo Galileo, and comprises scientific glass instruments that were produced in Florence since the second half of the sixteenth century [35].

Probably encouraged by the success of the world fairs since 1851, technical museums saw their heyday in the first half of the twentieth century: Before the destructions of World War II, almost 100 museums in Berlin were devoted to the history of technology. It took until 1982 to consolidate the remnants of these collections in the newly founded Deutsches Technikmuseum [36]. Here, glass only plays a minor role, and is better represented in the Museumsdorf Baruther Glashütte in the tiny village of Baruth, south of Berlin: an open air museum and industrial monument tells the story of glassmaking in this valley since 1716, it includes live glassmaking shows, and a permanent exhibition on Reinhold Burger, the inventor of the thermos flask [37]. Further to the West, the Gernheim Glassworks form part of the LWL Industrial Museums and are housed in an original glass cone of 1825. Production ceased in 1893, and the premises were turned into a museum in 1979 [38]. Together, Baruth, Gernheim, and the Glass factory Lamberts in Waldsassen applied for adding the manual production of mouth-blown hollow and flat glass to the German inventory of the intangible cultural heritage of UNESCO, and succeeded in 2015. The Continium discovery center in Kerkrade, The Netherlands, is a hands-on science museum that includes several historical collections. One of these is dedicated to glass, namely to the production of the Kristalunie glass factory in Maastricht [39]. Continium has been founded in 2009, based on a previous institution, the Industrien, which existed from 1994 to 2009.

A more prominent role is given to glass at the Deutsches Museum in Munich, which addresses the whole history of science and technology in Germany. It was founded in 1903 and has featured glass exhibitions since 1906. A room dedicated to glass technology in 1928 was destroyed during World War II. It was augmented into a department of glass technology that existed from 1959 to 1978, and was reinstalled in 1990 (Figure 3). The museum is working on a six-volume series on glass technology, of which four have been published so far [40, 41].

Some companies specialized in glass technology have founded museums of their own. A collection of optical instruments that was established by scientists of the Carl Zeiss company in Jena in about 1900 was turned into the Optisches Museum in Jena in 1922 [42]. The same city houses another glass technological museum, the Schott GlasMuseum und Schott Villa [43]. In Corning, New York, the Corning Glass Works (today Corning Inc.) established the Corning Glass Center in 1951, which

Figure 3 Deutsches Museum, Munich, entrance to department of glass technology, 2012. The white interior creates a demure and scientific atmosphere. Source: Photo: Deutsches Museum.

featured a Hall of Science displaying the proudest achievements of the company, as well as a more general museum of glass [44]. Today, the Glass Center has been completely incorporated into the steadily growing Corning Museum of Glass; the Hall of Science continues to exist within the museum as the Glass Innovation Center [45].

Probably the largest museum of glass technology is located in La Granja, Spain. The Technology Museum of Glass was founded in 1989 and is housed in the spectacularly well-preserved eighteenth-century factory buildings of the Royal Glass Factory of La Granja (Figures 4 and 5). It is dedicated to the methods of glass production of the eighteenth century, and includes both blown glass and stained window glass, the latter being represented by the workshop of the brothers Maumejean, a French–Spanish company of the late nineteenth and early twentieth centuries. The museum also includes collections of bottles from various European factories, as well as crystal from the La Granja production and contemporary glass art. It is accompanied by a glass school and a large studio glass workshop ([46] and P. Pastor Rey de Viñas, private communication).

4.5 Regional and Specialized Collections

It would be an insult to call the Rijksmuseum Amsterdam a regional museum. Yet its collection of glass truly reflects the taste for glass in a specific region of Europe, namely glass *à la façon de Venise* during the Golden Age of the Netherlands in the seventeenth and eighteenth centuries. The collection's roots lie in the Netherlands Museum for History and Art in Den Haag, which was incorporated into the Rijksmuseum in 1885. Glass is also being held in the collections of other national museums, such as the National Museum in Stockholm and the Musée d'art et d'histoire in Brussels.

Quite naturally, glass museums have been established in regions that experienced a concentration of glass industry in the past. The Museo del Vetro on the Venetian island of Murano, the Museo dell'Arte Vetraria Altarese in Altare (Italy), the Musée-Atelier du Verre in Sars Poterries (France), the Glasmuseum Frauenau in the Bavarian Forest (Germany), the Broadfield House Glass Museum in Kingswinford (Stourbridge, England,

now closed, but with plans to soon reopen under a new name: the White House Cone Museum of Glass), the Museu do Vidro in Marinha Grande (Northern Portugal), and the Shanghai Museum of Glass that opened in 2011 in the former Shanghai Glassware Factory in Shanghai are prominent examples. The important place taken by Nancy in Art Nouveau crafts, namely with the Gallé and Daum factories, is being represented in the glass collections of the Musée des beaux-Arts and at the Musée de l'École de Nancy.

In some cases, glass museums emerged from a single glass factory. One of the most famous of the late nineteenth and early twentieth century, Val-Saint-Lambert in Belgium, is currently being transformed into a "Cristal Park" with new business, residential, and leisure areas [47]. The project includes "Cristal Discovery," a glass museum that was opened in 1998 in the castle of Val Saint Lambert and is currently being augmented by a glass studio [48]. The St Helens World of Glass in Saint Helens (between Liverpool and Manchester in England) is an

Figure 5 Technology Museum of Glass, La Granja, Spain. East dome of the historical factory building with model of a glass furnace.
Source: Photo: Archive of the Fundación Centro Nacional del Vidrio.

Arts center that includes a small but distinguished museum incorporating The Pilkington Glass Collection [49]. Another example is the Glasmuseum Immenhausen, which is located in the former Süßmuth glass factory near Kassel, Germany. A few of these museums grew from local collections into museums of national rank, such as the Nationaal Glasmuseum Leerdam in the Netherlands, founded in 1953; the Finnish Glass Museum in Riihimäki (Finland), which opened in 1981; or the Swedish Glass Museum in the culture park of Småland in Växjö, which reopened in 1996 [50–52].

There are also active glass companies that have a glass museum of their own, such as Lobmeyr in Vienna, Moser in Karlovy Vary, and the Museo del Vidrio in Monterrey (Mexico), which opened in 1992 in the administrative building of Vitro [53]. The most venerable glass collections linked to glass producers are to be found in the United States, however. The Toledo Museum of Art was founded in 1901 by Edward Drummond Libbey

(1854–1925), owner of one of the largest glass factories in the United States at the time. Its glass collection is small compared to those of other museums, but outstanding in quality and scope, and was moved into a separate Glass Pavilion in 2012 [54]. Toledo as the cradle of the American Studio Glass movement in the 1960s brings to mind the Museum of Glass that opened in 2002 in Tacoma, Washington, USA. It is dedicated to international Studio glass art and closely tied to the regional glass scene around Dale Chihuly and the Pilchuck Glass School [55].

Many other specialized collections are focusing on contemporary glass, such as the Glasmuseum Ebeltoft (Denmark) founded by the Danish glass artist Finn Lynggaard (1930–2011) in 1985, the Alexander Tutsek Foundation in Munich, as well as the Glass Art Centre (Cesty Skla) that was established in 2006 in the František Glassworks in Sázava (Czech Republic), to collect and display works from the International Glass Symposia (IGS) in Nový Bor. In 2008, the European Glass Museum for Modern Glass opened in Rödental (Germany) as a branch of the Kunstsammlungen der Veste Coburg (Figures 6 and 7). Whereas the historical glass collection remains on view in Coburg castle, the new museum building is devoted to the more recent history of the Studio Glass movement, in which Coburg took a special part with the Coburg Glass prizes of 1977, 1985, 2006, and 2014 [56]. The Hokkaido Museum of Modern Art in Sapporo, Japan, has given particular weight to its collection of glass from the Art Nouveau period to today since it was founded in 1977. Since then, various other museums in Japan have built significant collections of Art Nouveau glass in particular, such as the Kitazawa Museum of Art in Tokyo with its outstanding collection of glass by Émile Gallé.

It is remarkable that some of the abovementioned museums (and many more that are not listed here) act privately and receive either very little public funding or none at all. Among the private museums, two institutions stand out for their large collections: The Glasmuseum in Passau (Bavaria) was founded by the collector Georg Hörtl (1928–2016) in 1985 and is specialized in Central European glass of the eighteenth and nineteenth centuries. It owns about 30 000 vessels, of which 15 000 – a record among glass museums – are on permanent view [57]. Equally sizeable is the Hempel Glasmuseum, founded by J. C. Hempel in Nykøbing (Denmark) in 1964 [58]. It is specialized on the history of glass in Northern Europe from the Renaissance to the nineteenth century, and reaches out into contemporary art by presenting each year the Hempel Glass Prize to young Danish glass artists.

The field of stained glass is a subject of its own. The Deutsches Glasmalereimuseum Linnich (located between Aachen and Düsseldorf) is dedicated to collecting and

Figure 6 European Museum of Modern Glass, Rödingen, Germany. By making ample use of glass for its architecture and interior, the museum achieves a space that is uniquely transparent and full of natural light. *Source:* Courtesy of Kunstsammlungen der Veste Coburg, *Photo:* Lutz Naumann.

presenting stained glass – a rare specialization, which it shares with The Stained Glass Museum in Ely Cathedral, England. The Deutsches Glasmalereimuseum is situated in a region of stained glass production that is still active today, such as Derix in Kaiserswerth and Kevelaer, and Oidtmann in Linnich.

5 The Corning Museum of Glass

The Corning Museum of Glass is one of a kind: It is regional as well as international, combines many special collections under one roof, including a large technical section, has a significant archeological collection, and

education is one of its main priorities. Above all, it is an institution of its own, solely and entirely dedicated to the history of glass.

The museum was founded in 1951 as part of The Corning Glass Center that was built by Harrison & Abramowitz (see Section 4.4). It has always been closely tied and funded by The Corning Glass Works (today Corning Inc.) [59, 60]. It owes its existence to Arthur A. Houghton (1906–1990), one of the owners of The Corning Glass Works. Houghton had been president of the Steuben glass factory, was an expert in rare books (he endowed the Houghton Library at Harvard University), and maintained leading positions on the boards of cultural flagships such as The Metropolitan Museum of Art, the New York Philharmonic Symphony Society, and the

Figure 7 European Museum of Modern Glass, Rödingen, Germany, whose 2008 building acts as a monumental showcase. *Source:* Courtesy of Kunstsammlungen der Veste Coburg, Photo: Lutz Naumann.

Pierpont Morgan Library. Against such a background, it becomes clear that The Corning Museum of Glass was not devised as a provincial company museum. From the onset, the museum became a center for the study of glass from various periods, and has published the *Journal of Glass Studies* since 1958. The acquisition of its important glass collection was paralleled by the growth of the museum library, which was commissioned quite simply to collect every available publication on the history of glass. The library was renamed in 1984 The Juliette K. and Leonard S. Rakow Research Library of The Corning Museum of Glass, and moved into a building of its own in 2001. Today, it is undoubtedly the largest library of its kind, and it has been extended into the collection of archives and the hosting of exhibitions of its own [61].

The development of The Corning Museum of Glass and its library suffered a devastating setback in 1972, when the Chemung River flooded the town and the museum. Since then, the museum has recovered, thanks to unfailing support of the company, and undergone several expansions: 1980 (the Gunnar Birkerts building), 2001 (Smith-Miller + Hawkinson building), and 2015

(Thomas Phifer, Contemporary Art and Design Wing) (Figure 8). Today, the museum owns about 50 000 objects and welcomes about 400 000 visitors each year. With a permanent as well as a number of mobile glassmaking theaters, including demonstrations on ship cruises, with a large glass market, and with The Studio, which opened in 1996, The Corning Museum of Glass offers an experience that goes far beyond the mere display of its glass collection.

6 Glass Museums: Purpose and Concerns

The number and variety of glass museums and museal glass collections continues to grow and evolve. Many successful museums have indeed shown that glass can attract a wide range of visitors, especially if contemporary glass sculptures are on display, and even more so, if the museum offers the additional opportunity of watching glassmaking live.

Figure 8 Aerial view of the Corning Museum of Glass, Corning, New York, USA, showing the impressive dimensions of this museum dedicated exclusively to glass. To the left, the Birkerts building of 1980 with its characteristic shape that symbolizes the flow of hot glass. To the right, the annex of 2015, which replaced most of the recently closed Steuben factory. At the bottom, the main museum entrance. Source: Photo: Iwan Baan.

Visiting a museum – not only those specialized in glass – has become an event, a weekend attraction for the whole family. ICOM's definition of the purposes of a museum, quoted at the beginning of this article, mentions "enjoyment" only in third place, after education and study. But it seems that in reality, joy – or rather, the "fun" of experiencing a pleasant distraction from one's daily routine – have conquered the first place. Since the museum budgets are closely tied to the number of visitors, there is an interest to increase visitation continuously – by offering a lively program of special exhibitions and of attractive events. Museums tend to accept this development, as it helps to provide the necessary funds for the more serious aspects of a museum – acquisitions, conservation, research, and education. These pillars need to be kept solid, to avoid turning museums gradually into theme parks.

7 Perspectives

While museums are becoming more and more popular, their purpose seems less and less clear. There is a tendency toward an undifferentiated enshrinement of the

past [62]. Glass museums have the privilege to tell the world about glass. But the question needs to be raised, and answered, why the world needs to know. A strong case should be made for telling the story of a material that has accompanied mankind through most of its history of technological progress and continues to be essential for our life today.

Glass museums need to address a number of phenomena that are specific to their subject. There is, for instance, the fundamental shift of categories between the older tradition of glass vessels as more or less utilitarian things, and the advent of modern glass sculptures as works of art. A glass that has been used by a seventeenth-century Dutchman to drink beer may be acknowledged as a cultural or social document, appreciated as a good piece of design and craftsmanship, and compared to glass vessels from other periods in history (Figure 9). In the context of modern works of glass sculptures, it can even be looked at as a work of art; but such a modern projection has little or nothing to do with the original intentions of the maker and the first users. These lines can easily become blurred in the artificial settings of glass museum displays.

If we look at the older tradition of glassmaking only, we are faced with nuances that pose a challenge even to the

Figure 9 Beer glass, reputedly found in Dordrecht, The Netherlands, probably made in Rotterdam, first quarter of the seventeenth century. Kunstpalast, Glasmuseum Hentrich (Gl 2011–2026 e). Source: Photo: Kunstpalast.

expert. To distinguish vessels that were very common and ordinary in their time from the more exceptional masterpieces can be quite difficult. Moreover, the common vessel could have traveled into a different cultural context and thus become a precious rarity after all. How should this and much more be communicated to the visitor?

As for modern glass art, there is a tendency among glass museums to compete in collecting Studio glass; and glass artists, steadily growing by number as well as by quality of craftsmanship, continue to cater to this demand. There certainly is a worldwide fashion, perhaps even a Studio glass craze. But looking ahead 20, 50, or 100 years of time: Will people then consider the vast accumulations of glass art a boon, or a bubble?

Concerns such as these make clear that glass museums, as everything else, must change over time, in order to keep their attractiveness to the public. But glass is a material that has caught the curiosity and imagination of the people for millennia, and still continues to provide a great technological challenge and potential. We can trust that it

will continue to provide plentiful fascinating content for the glass museums of the future.

Acknowledgments

This contribution has been sent to all members of the ICOM Glass committee. I received valuable input from my glass museum and glass research colleagues and thank in particular Milan Hlaveš, Reino Liefkes, and Teresa Medici, as well as Ayşegül Cihangir, Karin Dalskov, Susanne Evers, Eva-Maria Günther, Giulia Musso, Eva Nováková, John Parker, Paloma Pastor Rey de Viñas, Michel Polfer, Ulrike Scholda, and Hana Wollerová.

11.1

Postface – A Personal Retrospective

C. Austen Angell

School of Molecular Sciences, Arizona State University, Tempe, AZ, USA

As I look over the tremendous outpouring of intellectual effort, from talented scientists across the world, that has produced the contents of the *Encyclopedia*, I am humbled by the assignment I accepted to write, namely some concluding retrospective – something that might capture the essence of this science of glassy matter (and the liquid states that preceded them in most – but certainly not all – cases). It is a field so rich in content that it is small wonder that it holds the attention of nearly all who venture into it.

The author has had the privilege of working, now over a 60-year timespan, in a variety of aspects of the physics and chemistry of glass-forming liquids and their solid products where a particular condition of the liquid has become frozen in time and space by its glass transition. I still remember the sense of wonder I felt when, as a fresh PhD, I tested for myself the comment of David Turnbull, based on reports from Russian scientists, that certain mixtures of the simple salts, KNO_3 and $\text{Ca}(\text{NO}_3)_2$, yielded clear glassy solids when cooled from their liquid states. What could be simpler than a liquid with two cations, each with the argon electronic structure, and a compact triangular anion that compensates their positive charges? Where were the networks, or polymers, that I had always read were necessary to frustrate the crystallization process? And yet there it was. One could watch the rapidly increasing viscosity as the liquid cooled, and could pull beautiful long fibers from this collection of simple ions (*ionic argon*). Surely the viscous liquid and glassy states must be fundamental to understanding the physics of the liquid state that so many considered to end at the melting point. I became a life-long devotee of glass-forming liquids, and still salivate when I read of some synthesis that is producing an *oil*.

How strange it is that a liquid need only be 100 times as viscous as water at its melting point, to have difficulty crystallizing when cooling at moderate rates (e.g. in a vial plunged into liquid nitrogen for molecular liquids, or as a liquid poured onto a cold metal plate for higher-temperature systems), but then it requires another 13 orders of magnitude change in viscosity before the liquid can no longer adjust its structure to the decreasing temperature, and so gets “frozen in space-time” as a glass.

Sixty years amounts to some 12 generations of graduate students. Clearly there have been huge developments in the field in this period. The contents of the *Encyclopedia* stand as testimony to those advances, some of which would have been totally unexpected, whereas other have been more incremental, pushed by newly recognized needs.

Sixty years ago, the formation of bulk glasses from liquid metals was unknown, indeed the formation of *bulk* glasses that are metallic is of very recent origin. They were first reported in 1990 [1] by A. Inoue, coauthor of Chapter 7.10 on the subject in this volume.

Sixty years ago, the ability to simulate the formation of glassy states with fast digital computers was only a dream. It is now 40 years since first attempts to simulate the archetypal glass former SiO_2 were made with pairwise additive interaction potentials [2]. Chapter 2.9 by Kob tells how different things are now.

Silica glass is a remarkable material, which we have learned to pull into (polymer-protected) fibers of essentially theoretical strength. How could we imagine, 60 years ago, that our world would be connected by glass fibers of this composition, carrying information from one continent to another at the speed of light (in glass). It has been as major a revolution as that brought about by the harnessing of radiowaves much earlier.

Figure 1 Line of *bullet* voids in the center of the silica core of an optical fiber, resulting from passage of the 6000 K, ~5 GPa plasma through the fiber. The density and related properties of the residual silica have yet to be determined. *Source:* Reprinted with permission from [4] © Optical Society of America.

Another, more esoteric and so far little recognized, consequence of the science of optical fibers from silica (with claddings of Ge-doped silica that confine the transmitting energy to the core of the fiber), has been the fabrication of a mini-laboratory for potential ultrahigh temperature and pressure science. This has been demonstrated by Kashyap and coauthors [3] following their findings of the *optical fiber catastrophe* in which a plasma, initiated by a defect or a blockage in the fiber, ignites and moves back through the fiber toward the light source at a velocity controlled by the fluence, creating briefly a zone of temperature in excess of 5000 K (depending on the fluence) and enormous pressure confined by the cladding, which can evidently withstand some 7 GPa (Figure 1) [4, 5].

This observation bears on one of the really unexpected things that has happened, in the second half of our 60 years – and one that is still a subject of much controversy. This is the finding that certain glass-forming substances, pure substances, can form more than one sort of glass. Called *polyamorphism*, this is now well established as a phenomenon in computer-simulation studies [6, 7], but remains subject to much uncertainty in laboratory studies, mainly because of its close (and understandable) association with crystallization [8]. There is a nice

Figure 2 Enthalpy spike occurring just after the glass transition of quenched D-mannitol, producing the second amorphous phase whose X-ray radial distribution function (Figure 3) is virtually identical to that of the initial glass, and totally distinct from that of the crystal.

Chapter 3.9 on the subject by McMillan, who coauthored the first paper on this phenomenon after Mishima's seminal observation on glassy water [9].

The most recent (and perhaps the cleanest) example may be that involving a polyalcohol (D-mannitol, an optical isomer of the much-studied 6-carbon, 6-alcohol sorbitol). D-mannitol needs fast quenching to vitrify, but then, during reheating through the normal T_g , it transforms sharply to a second more stable glassy form that has a lower density (Figure 2) [10, 11]. The two different glasses of the same substance have almost indistinguishable XRDs (Figure 3) but rather different enthalpies [10]. When converted to an entropy and inserted into the well-known Adam–Gibbs equation,

$$\tau = \tau_0 \exp(C/TS_c), \quad (1)$$

Figure 3 The X-ray diffraction patterns of D-mannitol in the crystalline and two different amorphous states separated by the first-order transition seen in Figure 2. *Source:* After [10].

the decrease in enthalpy observed surprisingly implies that the second polymorph formed in the transition should have a relaxation time orders of magnitude longer than that of the parent liquid – which means far longer than that of the first glass at its glass transition temperature. How could this happen? The answer should be that it is the result of the nucleation of a phase having a substantially lower chemical potential than that of the phase from which it nucleated. As a result, diffusion across the phase boundary would be a much faster (free energy *downhill*) process than diffusion within the body of the first glass formed.

Another and possibly related finding of high interest has been that, in a majority of glass formers of the molecular variety, one can obtain in an unexpected way, glasses (necessarily in small amounts) of very different properties – like those of glasses that would be formed by millions of years of slow aging. Here, vitrification proceeds via vapor deposition onto a substrate whose temperature is controlled to lie a short distance below the normal T_g . This discovery by the Ediger-Yu groups [12], who named these materials *Ultrastable glasses*, was initially reported for the large organic molecule tri- α naphthyl benzene (Figure 4). It has since been reported also for a large number of organic glass-formers – but so far no inorganic cases. Since the ultrastable glasses have much higher moduli than their “normal” glass brothers, the prospect of making inorganic glassy films of high scratch resistance would seem to be an objective worth pursuing.

It is still unclear whether ultrastable glass formation is a phenomenon limited to glass formers of fragile character or not. Something very different happens in the case of the intermediate (hydrogen bonded) liquid glycerol [13] and some relatives, whereas no such behavior is seen in the case of water, which is a very strong liquid near the glass transition.

Figure 4 First demonstration by differential scanning calorimetry of the large enthalpy deficit and relative kinetic stability of an ultrastable glass of tris-naphthylbenzene. Source: After [13].

These features remind me of the breakthrough in the problem of residual entropy of ice, due to proton disorder, that was largely resolved by the famous work of Suga and coworkers. These authors [14] found a way to unlock the kinetics of transition to a lower entropy (proton-ordered) state of the ambient-pressure ice crystal. It seems obvious to me that if such a state exists, the fastest way to reach it must be by a process of nucleation and then growth down the free energy gradient. But what is this if it is not polymorphism? We await transmission electron microscope studies of the early stages of growth of the ultrastable glass films. We already know that, in thick films of these glasses, the way back to the normal viscous liquid state is by this mechanism.

This latter may seem like an esoteric matter, but in these days of increasingly nanoscopic technology, it might be of vital importance. It is reported [15] that limitations on the fidelity of nano-mechanical and electro-dynamical devices are set by the white noise associated with the boson peak modes which, like the cryogenic anomalies, are greatly diminished in the ultrastable glass state. All indications are that this state is just a less disordered version of the normal glass, though there is some debate about the mechanism by which it is accessed. It is not necessarily a denser state, in fact the most nearly perfect glasses, in the sense of those with the least evidence of defects and excess entropy, are those with low-density open network structures, like water and a-Si. Hopefully, the future will yield a better understanding of the *perfect* glass state, and its accessibility or otherwise [15, 16]. From recent studies [17], it also seems possible that this sort of transition, although weaker and higher in temperature, is involved in the mechanism for fast digital switching in the so-called Phase Change Materials, which are obtained from a range of weakly metallic chalcogenide liquids that become semiconducting glasses on hyper-quenching and well-conducting crystals on controlled reheating – and are under development for ultrafast rewritable computer-memory technology.

And of course there were always “theories of glass” of different qualities. Despite all the progress that has been made, most would agree that we still do not have a satisfactory theoretical understanding of the process of vitrification, or why it occurs so suddenly in some liquids, the so-called *fragile* (or *short*) ones, and over such a relatively wide temperature range in other cases, like the archetypal *strong* (or *long*) glass former, SiO_2 . Diverging length scales have been popular as a concept but these are only proposed for four-point correlation functions that cannot be measured in the laboratory [18]. It does not help that the static quantity, the mean-square volume fluctuation derived from the measured isothermal compressibility from the Landau relation,

Figure 5 Isothermal compressibility data for various glass-forming liquids of organic and inorganic types, showing a consistent downward trend with decreasing temperature (Source: After [19]). Solid arrows: melting temperatures of crystals; dashed arrows: glass transition temperatures; PC: polycarbonate; star: 45 $\text{Cd}(\text{NO}_3)_2 \cdot 45 \text{KNO}_3$ at T_g ; (Ca,K) NO_3 : 61.9 $\text{Ca}[(\text{NO}_3)_2] \cdot \text{KNO}_3$.

$$\kappa_T = -1/V(\partial V/\partial P)_T = -\langle(\Delta V)^2\rangle/Vk_B T, \quad (2)$$

decreases with temperature as T_g is approached (Figure 5) for all the glass-forming liquids for which we can find data [19]. It implies that a static correlation length in all cases decreases going into the glass transition. This applies to the archetypal glass former, silica itself, in the observable range, though simulations suggest it may have an anomalous range at temperatures above that of its heat capacity maximum at $\sim 4500 \text{ K}$. Only occasional *anomalous liquids* like water and liquid tellurium (which are both exceptionally bad glass formers, i.e. especially fast crystallizers), behave otherwise in their observable temperature ranges [20]. But even these liquids would be expected to become *normal* at lower temperatures when approaching the glass transition if crystallization could be avoided.

Before leaving this retrospective, we should consider the limits on what sort of materials we are prepared to recognize as glasses for future consideration in our field. It is well known that there are important ergodicity-breaking phenomena in the field of magnetism and that spin glasses are a heavily researched subject for which advanced theories are available. However, the physical interactions between the elements of that class of substance are so different from those that determine the phenomenology of our field that I do not see much benefit in including their consideration in a work of this type. On the other hand, the research area of

orientationally disordered crystals seems highly relevant. These materials also conform to a strong/fragile pattern but, in contrast to glass-forming liquids, most examples fall at the *strong* end of the spectrum. Many prove to be just the low-temperature end of an order-disorder transition, which is very suggestive [21]. A good example of a classical order-disorder transition, interrupted by a “glass” transition is that of the bimetallic Co–Fe system depicted in the left-hand panel of Figure 6 for which the glass transition kinetics proves to be strictly Arrhenius, like that of an ideally “strong” liquid [22]. Likewise, we have been able to learn a lot from the study of colloidal systems, even though the interactions between particles are very different from those in structural glasses and temperature does not play the critical role we are accustomed to. Certainly these systems have ergodicity-breaking, and crystallization, as key phenomena, just as do our structural glasses. A chapter on these relationships in some future edition of the *Encyclopedia* would probably be valuable. In the same spirit, the cover page of the issue of *J. Phys. Chem. Glasses* for the Sheffield meeting celebrating the centenary of the Society of Glass Technology (Figure 6, which is taken from the opening talk of the Turner Symposium abstract) is indicating a willingness to consider glass transitions with suggestive forms in materials outside the norm of glass-forming systems.

Looking forward, there is nothing more certain than that there will continue to be surprises. Of high

PHYSICS AND CHEMISTRY OF GLASSES

European Journal of Glass Science and Technology Part B

Critical points in systems with glass transitions

100 Years of the Society of Glass Technology

Figure 6 Cover page of the centennial issue of the Glass Technology Society, featuring a figure from the Turner Symposium opening talk illustrating glass transitions in nonclassical systems with apparent critical or near-critical behavior. Source: Reproduced with permission of the Society of Glass Technology.

probability will be the finding of inorganic equivalents of the ultrastable glasses mentioned above, which have so far only been reported for molecular liquids that are fragile relative to the common inorganic glasses. Some of the less common high-modulus inorganic glass formers such as calcium aluminate and lanthanum borate [23] are very fragile in their liquid states and would make good candidate materials for ultrastable glass formation by sputtering onto hot sub- T_g substrates. Thin films of such materials could provide very high-modulus protective coatings and low-noise substrates for nano electronic devices. At a fundamental level; the enthalpy of solution of an ultrastable glass of composition near that of YAG

garnet (e.g. in the work of Navrotsky [24]) would be of high interest in the context of understanding the *perfect glass* problem [15].

Given the extraordinary interest in reticular chemistry generated in the last two decades [25], it will be surprising if some all-inorganic vitreous analogs that yield continuous films of high porosity at the nanometer scale, suitable for gas separations and other purposes, are not developed, though the high-temperature stable templates needed for their formation might be difficult to find. Active research in the field of "g-MOFs" is just beginning.

Also one might expect more interest in variable band-gap glasses formed by chemical vapor deposition on

controlled temperature substrates of compositions of similar crystal structure like the 3–5 and 2–6 wurtzite structures, e.g. GaN and ZnO, to cover the solar spectrum with weather-resistant photon absorbers. There are a large number of such open network structures that can be incorporated into such structures. Their mixtures should be much more tolerant of mismatch strain than are their crystalline equivalents. Likewise, the composition-dependent metal–semiconductor transitions in chalcogenide glass formers will lend themselves to further exploitation in the lower frequency domain.

Anything that one can try and guess at, here, will surely miss the mark of the important things to come from future generations of glass scientists, but one thing that we can be sure of is that those working in the field and making the new discoveries will feel as privileged to work in it as have we, i.e. those who have participated in the production of this *Encyclopedia*.

 Barometer, 1399–1401
 Basalt
 Geological glass: basics, 820; columnar jointing, 822; compositions, 198, 816; corrosion in seawater, 831; $\text{Fe}^{2+}/\Sigma\text{Fe}$ ratios, 204; flow, 429; iron redox reactions, 586, 588; NBO/T, 200; Pelé's hair, 821; volatile solubilities, 575, 578
 Glass fibers: mechanical properties, 1109; structural anisotropy, 403
 Lunar glass, 805
 Raw material in glassmaking: for bottles, 1422; stone wool, 42, 1103
 Synthesis in Mesopotamia, 1415
 Vitrification: effect of cooling rate, 1422
- Batch
 Composition: calculation: 55–56; final adjustment, 57; redox factors, 57
 Enthalpy of melting, 64
 Loading, 1155
- Batteries, *see* Sulfide glass electrolytes
 Belus river, in Pliny's account of glassmaking, 1235, 1261
 Bending: cold, 1085; of laminated glass, 1100; tests, 926
 Bioactive glasses, 991
 Bioactivity: angiogenesis, 996; apatite formation, 994–97; effects of network-modifier cations, 997; effects of network polymerization, 996; ion release upon dissolution, 995; osteoblast turnover, 996; sol-gel vs. melt derived glasses, 996
 Chemical composition and structure, 992
 Commercial products: Bioglass 45S5, 991–1000; Biogran, 998; BonAlive S53P4, 998; Dinorex, 399; ICIE1-F1, 992, 997; Mirragen, 1001; NovaBone, 998; NovaMin, 998; PerioGlas, 998; S53P4, 991; TheraSphere, 1001; Vitryxx, 1001
 Hybridization with organic glasses, 999, 1001
 Mesoporous silica nanoparticles for drug delivery, 993
 Synthesis: controlled crystallization, 999; sol-gel reactions, 993–94
 Uses: anti-bacterial action, 999; dentistry, 999–1000; miscellaneous: 1001–02; oral care: 1001; orthopedics (e.g. cancellous bone repair, spinal fusion), 998; phosphate boluses, 1001; scaffolds for bone regeneration, 994, 999
- Biogenic silica glass, *see* Diatoms, Flint, Phytoliths, Radiolarians, Sponge spicules
 Biological and ecological importance, 955; silicon cycle, 964; SiO_2 vs. CaCO_3 , 964
 Biological synthesis: condensation reactions, 962
- Birch-Murnaghan equation of state, 308
 Blowpipe, 1287, 1296
 Bodenstein number for reactor convection/diffusion 1171
 Bohemian glass: 1337, 1399, 1423, 1445
 Borate glasses
 Properties: Arrhenius parameters for diffusion in, 469, 471; composition dependence of T_g and fragility, 216; mixed alkali effect, 472; optical basicity, 599, 602; pressure dependence of diffusivities, 473; radiation-induced damage, 409; thermodynamic models, 550; vibrational spectrum, 292; viscosity, 438
 Structure: borate network, 136; borate superstructural units, 138, 212; boron coordination in alkali borates, 137, 227; color and coordination of transition elements, 680–87; dynamical heterogeneities, 506; infrared spectra, 152; mixed B,P network in borophosphates, 903; network depolymerization, 176–77; ultrastable glass, 1461
 Uses: bioactive glasses, 1001; laser-active glasses, 702
- Born-Mayer-Huggins interatomic potential, 223
 Born-Oppenheimer approximation, 223, 234
 Boron oxide, B_2O_3
 Properties: flux in glassmaking, 30; heat capacity in the glass transition range, 12; vibrational spectrum, 294; viscosity, 438
 Structure: borate network, 136; boroxol rings, 138; molecular dynamics simulations, 227

Borosilicate glasses

Chemistry: compositions, 868; durability, 642
 Phase equilibria: liquid-liquid unmixing, 33, 541, 868; Na_2O - B_2O_3 - SiO_2 phase diagram, 33, 541, 868
 Structure: boron coordination, 871; boroxol rings, 138, 175; color and coordination of transition elements, 680–87; first-principles simulations, 237; network connectivity, 873; pressure and temperature dependences of connectivity, 875; Pyrex, 871; role of aluminum, 874; Si,B mixing, 872; superstructural units, 873

Structure-property relationships: boron anomaly on viscosity, 442; configurational heat capacity and entropy, 177; on diffusion, 471; thermal expansion, 35; Vycor, 870

Uses: early products, 867; modern products, 869, nuclear waste storage, 869, 1208; pharmaceutical glasses, 879; Pyrex, 867; reinforcement fibers, 95; Vycor, 869

Boson peak: first sharp diffraction peak, 189; hyperquenched glasses, 354; metallic glasses, 188; oxidized glasses, 296, 320–22; silica glass 188, 296; universal representation, 322

Bridging and nonbridging oxygens, 178

Bubble: component of *Pâte de verre*, 1355; effect on thermal conductivity, 495; on viscosity, 447; formation upon sand dissolution, 61; glass defect, 54, 68, 675, 1110, 173; growth in decompressing magma, 821–24; indicator of glassmaking process, 1285, 1290, 1344; nucleation on CaCO_3 crystals in beverage containers, 644; opacifier, 1312, 1320; presence in extraterrestrial glasses, 808; radiation-induced defect, 408; rising velocity in a melt, 62, 435, 447; stirring agent for melt homogenization, 58, 118, 1154, 1213

Bubble level, 1387

Byzantine: alchemy 1280, 1345; art imitated in Venice, 1330; art pieces in Western Europe, 1442; champlevé enamels, 1320, 1321; colored glazing, 1341; gilded and silvered mosaics, 1331; mosaics, 1267, 1345

C

Calcium carbonate

Biogenic production: amorphous precursors, 5, 964; animal shells, 5

Component of eastern mediterranean silica sand, 1261

Corrosion-induced precipitation, 643, 644

Glassmaking: batch decomposition, 59; need for water resistance, 1420

Came, for stained-glass leading, 1353

Carcaise, annealing lehr, 1372

Cathode-ray tubes, 789, 1405–1406

Cerium oxide: chemical agent, 947, 1116; precipitation in nuclear waste glass, 1212; polishing agent: 643, 757

Chalcogenide glasses, 721

Glass: formation in S-, Se- and Te-based systems, 726; GASIR commercial product, 728; mechanical properties, 384, 731; T_g constraints for applications, 730

Structure: GeSe_4 and AsSe_3 building blocks, 725; network connectivity with Se chains, 138, 728; models from topological constraint theory, 213; NMR determinations, 729

Transparency: in the mid-infrared, 730; controlled ceramization improvements, 730, 731

Uses

Optical: fiber evanescent-wave spectroscopy, 731; fibers for space exploration, 731; infrared lenses and cameras, 730

Optoelectronics, *see* Optoelectronics, active chalcogenide glasses

Others: phase-change memories, 462; possible photo-darkening, fluidity, expansion, and crystallization materials, 733

Chemical analyses and characterization, 515, 516, 1345

Analyses

Inductively coupled plasma (ICP) spectroscopy: principle, 518; ICP mass spectrometry, 519; ICP optical emission spectroscopy, 519

Microprobe analyses: electron probe microanalyses, 521; secondary ion mass spectroscopy, 521

Miscellaneous: atomic absorption spectroscopy, 520; gravimetry, 517; specific methods for: boron, 521; ferrous iron, 523; fluorine, 523; lithium, 523

Scanning electron microscopy: energy-dispersive X-ray spectroscopy, 161; wavelength-dispersive, 161

X-ray fluorescence: basics, 517; energy-dispersive, 518; portable energy-dispersive, 1243; wavelength-dispersive, 518

Characterization

Corrosion resistance to: acids and alkalis, 524; lead and cadmium leaching, 524; water (hydrolytic), 523, 644, 884

Defects: laser-induced breakdown spectroscopy, 525; micro X-ray fluorescence, 525; scanning electron microscopy: 525

Chemical compositions

Historical glasses

Ancient: early bronze age, 1253; Roman, natron-based, 1262; Roman, opacified, 1266

Medieval: enamels on metal, 1321; glaze on terracotta, 1323; porcelain glaze, 1313; stained glass, 1345–46; window, 1346

Venetian: natron-type, 1330; opaque white, 1334;

Renaissance clear, 1333; Renaissance colored, 1336

Industrial glasses

Common types, 28, 198

Chemical compositions (*cont'd*)

- Families: bioactive, 992; borosilicates, 868; metallic, 920, 927; oxynitrides, 895; pharmaceutical, 881; phosphates, 907, 911; slags, 846; water glass, 860
- Fibers: mineral wools, 1104; 1107; reinforcement: 95
- Heterogeneous products: glass-ceramics, 939, 941, 1007, 1009; silica aerogels, 982
- Light-related glasses: color cathode-ray tubes, 790; frit for flat-display panels, 792; lighting, 777
- Waste immobilization glasses: municipal and industrial, 1194–97; nuclear, 1209
- Natural glasses: extraterrestrial, 803; geological, 198, 816
- Pigments, 1318–19
- Polymers, 1044–45
- Raw materials, 41–43

Chemical diffusion, 477

- Basics: effective binary diffusion coefficients, 399, 480; Fick's laws, 478; measurements, 478; tracer vs. chemical, 479
- Fick-Onsager approach: chemical potential gradients, 480; diffusion matrix, 481; diffusion path, 482; uphill diffusion, 481
- Real systems: coupled fluxes in aluminosilicates, 482; diffusion paths, 483; temperature dependence, 483

Chemical durability

- Hydrolytic stability: characterization, 23, 644, 884; pH dependence, 36
- Of: chalcogenides, 721; glass-ceramics, 945; nuclear waste glasses, 1210; phosphates, 712; soda-lime silica, 641, 883, 887; water glasses, 858

Chemical Oxygen Demand, 45

Chemical vapor deposition

- Processes, 764
- Uses: amorphous ice synthesis, 415; band-gap glasses, 1461; refractive index gradients, 673; SiO₂ fiber synthesis, 715–716; strengthening coatings, 91, 402; thin films, 763

Chill marks, 1288

Chromatic aberration: discovery, 1391; explanation, 673; practical correction, 1394

Coatings, *see also* Glazes and enamels

- Processes: history, 1136–39; hybrid inorganic-organic glasses, 1061–65; sol-gel, 978; thin films, 766
- Uses: antireflective, 771; container, 91, 402; LED, 911; low-emissivity, 770; multilayer interference, 771; optical fiber protection, 717; photonic crystals, 977; photovoltaics, 1114; strengthening, 389, 401

CO₂ emissions: batch melting, 44, 59; effect of cullet recycling, 1187; reductions through glass improvements, 391, 1095, 1103, 1113

Colburn updraw processes for flat glass, 70

Color, bulk, 677

Basics: crystal-field orbital splitting, 680; light absorption and transmission, 677; transition elements, 679

Cations in glasses

- Coordination: numbers, 680; octahedral and tetrahedral, 680; trigonal bipyramidal, 684; relationship with network polymerization, 680
- Sites: distribution, 680, 683; double, 686; single, Cr³⁺, 684; variations with composition, Ni²⁺, 682, 683; *silent* species, Co²⁺, 684, thermal expansion, 687

Mechanisms

- Atomic-like transitions, 4f lanthanide elements, 679
- Crystal-field transitions, 3d transition metal elements, 682–88
- Intervalence charge transfer: electron transfer between different valences, 680, 688; examples: Fe²⁺, Fe³⁺-bearing glasses, 688; Fe,Ti orange lunar glasses, 689
- Ligand to metal charge transfer: electron-density shift to a neighboring ion, 680, 688; examples: Fe²⁺ amber chromophore, 688; vanadate, uranyl, chromate groups, 688
- Nanophase formation: Ag⁰, AgCl, Au⁰, Cu⁰ nanoparticles, 594, 690, 1266; organized nanoclusters in low-alkali glasses, 689; photochromic glasses, 690
- Variations of coloration with: glass composition, 682, 685; redox state, 683; site geometry, 684, 685, 686; temperature, thermochromism, 687

Coloring elements, *see also* Pigments

- Ancient: Antiquity, 1415; *ferreto*, 1349; Roman glasses, 1266: Co²⁺, deep blue, Cu²⁺, turquoise or green, amber, ferrisulfide chromophore, 1266; opaque red, Cu⁰, 1266; in Lomonosov's synthesis, 1423
- Modern; analyses, 520; iron oxides, 45; transition elements, 679, 1318

Compliance, 340

Compressibility, *see* Volume properties

Computer simulations in glass processes, 111, 1173

Furnaces, *see below*

- Overview: data management, 123–24; fundamental steps, 111; objectives, 111; physical factors: advection and diffusion, 113–15; radiative heat transfer, 116; turbulence, 115
- Simulations: boundary conditions, 117; conservation equations: 113; discretization methods, 116

Conchoidal fracture, 383, 824

Configurational

- Changes (degrees of freedom), 7, 14, 263, 331
- (or potential) Energy landscape: basins: 17, 217, 363; megabasin separation, 352
- Properties: definition, 13, 331, 1430; enthalpy, 264; entropy, 17, 217, 264, 325; heat capacity, 15, 257, 324; residual entropy, 262, 314, 325; volume, 15, 16, 303

Container fabrication, 81

- General: ancient processes, 1285, 1375; from tubing, 881; world production, 92
- Individual Section machines: components, 81; families, 89–91; overview, 82, 92; working principles, 81, 88
- Machines: blow & blow, 84; press & blow, 85–87; narrow-neck & blow, 86–88; productivity improvements, 89; progress expected, 92
- Operations: cullet recycling, 1182; forehearth and feeder, 87; gob deformation, 84; gob feeder, 1380; heat management, 82; mold-glass interface reactions, 83
- Post-molding operations
- Cold-end handling: coating deposition for strengthening, 91, 389, 402; optical inspection 91; strength checks, 91
 - Hot-end handling: annealing, 91; coating deposition (SnO_2 , TiO_2 , $\text{TiO}_2\text{-SiO}_2$), 91
 - Post-production corrosion, 643
- Coordination numbers: composition changes, 135; for glass formation, 130; ion values, 20
- Copper nanoparticles, coloring effect, 1266, 1336, 1349
- Corning Inc
- New products: #7059, 793; Corex, 908, DICOR, 1006; electrofused refractories, 1374; glass-ceramics, 938; Mount Wilson Observatory mirror, 1395; Nonex, 776, 1424; Pyrex, 868; Vycor, 869
 - Processes: blowing machine for electrical bulbs, 778; fusion downdraw for flat glass, 77
- Corning Museum of Glass, 1450
- Corrosion reactions, 639, 647, 831
- Chemical analyses, 650, 652
 - Chemical reactions: first insights, 1329; in basic media, 640; neutral or acidic media, 639; precipitation of CaCO_3 or Na_2CO_3 : 643, 644; production of water glass, 857
 - Dissolution rates: effects of chemical affinity and pore closure, 659; composition, 658; pH and temperature, 659, 1111; measurements, 657; stoichiometry, 658
 - Hydrolytic resistance, 523, 644, 884
 - Influence of composition: borosilicates, 642; insulating fibers, 642; lead, 641; natural, 831; nuclear-waste storage, 1210; pharmaceutical, 644, 883; soda-lime, 641
- Models
- Complex hybrid: diffusion and dissolution fronts, 652; interdiffusion, 650; preferential dissolution, 650
 - Coupled interfacial dissolution-reprecipitation: chemical gradients, 652; dissolution-reprecipitation, 653
 - Leached-layer: gel, 648; interdiffusion zone, 648: leached layer, 639, 648
 - Stress corrosion: chemically assisted crack growth, 387; in glazing, 1073, 1077, 1085; reinforcement fibers, 108
- Cretan *pyxides*, vessels 1294
- Cristallo*, Venetian, 1331
- Crown
- Dental, 1006
 - Furnace part: 55, 1154, 1156, 1170, 1366
 - Glass, traditional: composition, 512, 668, 1391, 1424; fabrication, 1343, 1370; first optical fiber, 705; maximum size, 1405; optical properties: 674, 690; quality, 1344, 1391; relative permittivity, 1409
- Crystal glass, *see* Lead-bearing silicate glasses
- Crystal nucleation and growth, 511, 559
- Crystal-glass interface, 127
- Growth
- Mechanisms: normal, 564; screw dislocation, 564; two-dimensional, 564
 - Morphologies, 565
 - Rates: Wilson-Frenkel equation, 252
- Nucleation, classical theory: critical nucleus size, 560; Gibbs free energy of critical cluster formation, 560; interfacial energy, 560, 563; nucleation rate, 561; nucleus growth rate, 564; Ostwald step rule, 563; steady-state, 562
- Overall crystallization: Johnson-Mehl-Avrami-Kolmogorov approach, 252, 565; Time-Temperature-Transformation diagrams, 567
- Processes in: geological glasses, 822; glass-ceramics, 939–42
- Crystal palace, glass panes, 1371
- Cullet, 1179
- Applications, 1183; container glass, 1160, 1182; energy savings and reduction of CO_2 emissions, 44, 1169, 1187; European statistics for container glass, 1181; from float-glass production, 74; goals, 1180, 1188; national recycling rates, 1192
 - Categories: pre-consumer, 1180; post-consumer, 1180
 - Quality issues: car glazing 1096; lead-glass, 1186; rejects, 1185–87; scrap, 1183; sorting machines, 1184
 - Recycling: in Antiquity, 1269; Islam, 1330; Venice, 1329; from municipal waste, 1181
- ## D
- Dealkalization, surface, 399, 401, 645, 752
- Débiteuse, updraw processes for flat glass, 70
- Deborah number, 445
- Debye model, heat capacity, 217, 289, 321
- Defects: beads, with gas inclusions, 48; bubbles, 54, 68, 675, 1110, 1187; knots, 47; nickel sulfide inclusions, 48, 398; stones, 46; 1187 streaks, 68, 525; strength-controlling, 383; striae, 1110, 1362; 1391; undissolved crystals, 47; veins, 1362, 1392
- Delamination, surface, 753, 885

Fabrication: containers, 81, 879; flat glass, 67; glass-ceramics, 937, 1005; mineral wools, 1103; reinforcement fibers, 95; sol-gel products, 969

Glass, Roman, 1261, 1285

Artifacts or ingots from wrecks: Ajaccio, Corsica, 1342; Îles Sanguinaires, Corsica, 1233; Julia Felix, Adriatic, 270; Les Embiez, Côte d'Azur, 1233, 1263, 1286

Coloration: Cu⁰ nanoparticles, 1266; decoloration, 1263; opaque, 1266; redox control, 1266; transparency 1265

Compositions: control, 1265; natron-based, 1262; opacified, 1266; provenancing, 1263

Production means: cullet recycling, 1269; natron, 1261; melting furnaces, 1262 1277; tank furnace, 1263; workshops, 1264, 1268

Production operations: blowing: 1267, 1277, 1295; gathering, 128, marvering, 1287; sagging, 1286

Products: decorative artifacts, 1269; Lycurgus cup, 1266; mirrors, 1236, 1269; mosaic-footed bowl, 1267; pharmaceutical ware, 1279; Portland vase, 1300; vessels, 1268; window panes, 1269, 1342

Glass science, history, 1413

Antique and medieval concepts

Egypt, 1274, 1416

Greece and-Rome: alchemical background, 1276–78; Aristotle on viscosity and viscoelasticity, 1416; glass vs. metal, 1416; Greek philosophy of matter, 1275–80; Theophrastus on glass definition, 1414; on slags and obsidian melting, 1416

Islam, 1417

Mesopotamia, 1273, 1415

Western Europe: glassmaking, Isidore's account 1417; technical descriptions, Theophilus, 1418; views on the kinship of glass and igneous rocks, Marius, 1418

Chemistry: chemical analyses, 1424; chemical elements: alkaline earths, 1418; alkalis, 1421; silicon, 1414, 1421; Leblanc process, 1420; oxides/earths, 1421

Devitrification: glass ceramics, Réaumur porcelain, 1422, 1423; crystal nuclei, 1422; homogeneous, heterogeneous crystallization, 1422

Glass definition, difficulties, 1414; new proposition, 1415

Glass transition: Descartes' picture, 1419; influence of cooling rate, 1415; Kauzmann paradox, 1431; kinetic nature, 1422; residual entropy, 1428; thermal observations, 1427–29

New glass compositions: B₂O₃, 1424; basalt, 1422; Bohemian, 1423; borosilicates, 867; flint, 1423; Graham's salt, 1424; P₂O₅, 1424; SiO₂, 1422; systematic investigations, 1423, 1424; water glass, 857, 1423

Physical chemistry: high-temperature scale, 1425; liquid immiscibility, 1425, 1433; optical properties, 1424; permanent compaction, 1430; phase-equilibria determinations, 1425; relaxation studies, 1430; VFT equation, 1431; viscosity measurements, 1425

Strengthening: *Lacrymae batavicae* (Prince Rupert's drops), 1419; stress and rupture analysis, 1425; surface defects, Griffith theory, 1426; tempered glass, 1426

Structural studies: field strength, 1433; microcrystalline model, 1429, 1431; NBO/T, 1433; Raman spectroscopy, 1433; X-ray diffraction, 1432; Zachariasen's model, 1432 1431

Glass, scientific tool, 1387

Barometry

- Experiments: siphons, Baliani, 1400; springiness of air: Boyle, 1402; Torricelli's tube, 1400; vacuum into vacuum, Pascal, 1401; water pressure at high temperatures, Dulong and Arago, 1403
- Implications (Pascal): existence of vacuum, 1401; hydraulic press, 1401, 1402; weight of the atmosphere, 1401
- Pressure: air, Pascal, 1401; blood, Hales, 1404; hydrostatic, Pascal, 1401; sap, Hales, 1403, 1404
- Chemistry
- Glass assets: shapability, 1399; transparency and chemical inertness, 1397
- Glass corrosion: Boyle on water transmutation into earth, 1397; Lavoisier's refutation, 1397
- Glass types: Bohemian glass, *Kaliapparatt*, 1399; borosilicates, 1399; silica, 1399
- Glassware: Greek, 1395; alchemical, 1395, 1396; Lavoisier's, 1398; *philosophical egg*, 1396; vessel types, 1397; urinal, 1397
- Electrostatics: conductors and insulators, 1404; vitreous and resinous electricities, Du Fay, 1404; Leyden jar, 1405; electrostatic machines, 4, 1405; Lomonosov praise of the lightning rod, 1408
- Optics
- Glass: *flint* heterogeneity, 1394; *flint* making, 1394; Guinand homogenization process, 1394, 1395; implications for the achromatic lenses of refractors, 1408; mirror silvering, reflecting telescopes, 1395; modern coatings, 1409; Mount Palomar instrument, 1395
- Light: dispersion, 1392; nature of light, Newton, 1392
- Microscope: compound instruments, Kepler, 1391; Hooke, *Micrographia* observations, 1392, 1393; magnifying lense, Leuwenhoek descriptions, 1392, 1394, 1409; medical observations, 1409; petrological observations, 1409
- Refraction, experiments: chromatic aberration, 1391; distorting effects of glass on vision, Seneca, 1388; al-Haytham *Optics*, 1388; Ptolemy on air, water and glass, 1388, 1389; rainbow, Dietrich of Freiberg and al-Fârisî, 1390
- Refraction, theory: key phenomenon for applications, Bacon, 1389; law, empirical formulation and theoretical derivation, Snell and Descartes, 1391; refractive index, Young, 1391
- Telescope: beginnings, 1390: Galileo's heavenly observations, 1390, 1391
- Subatomic physics: discharge tubes, Geissler, 1405; electron, Thomson, 1408; radiant matter, Crookes, 1406; X-rays, Röntgen, 1406, 1407
- Thermometry: ancient forerunners, 1399; Galileo's thermoscope, 1399; thermometers, 1399, 1400
- Glass transition, 273
- Experimental
- Observations: calorimetric, 9; dilatometric, 9; initial, 1427–29; kinetic phenomenon, 7, 1422; of plastic crystals, 12; volume effects, 9; thermal diffusion effects, 496
- Variations with: frequency, 9; observational timescale, 11; pressure, 11; thermal history, 12, 1428
- Ideal*, 275, 458
- Microscopic picture, 15, 1419
- Theories: Adam-Gibbs, 275; configuron-percolation, 255; fast and slow modes, 273; free volume, 276, 281; insights from Molecular Dynamics simulations, 509; mode-coupling, 277; random free-order, 277
- Thermodynamic aspects: communal entropy, 282; driving forces for relaxation, 280; entropy creation, 268, 314; irreversibility, 11, non-equilibrium thermodynamics, 261, 266, 278
- Glass transition temperatures
- General: Kauzmann formula, 249; pressure dependence, 11; standard T_g , 9
- Values for: amorphous ice, 416, 419–24, 426–27; chalcogenides, 731; fluorides, 731; metallic glasses, 921; optical-fiber glasses, 712; polymers, 1039, 1044, 1053; solar-energy glasses
- Glass wool, *see* Mineral wools
- Glazes and enamels, 1309, 1310
- Basics
- General: definitions, 1309; final aspect, 1311; firing defects, 1311, 1312; micro- and nanostructure, 1315, 1317; opacifier use, 1322; substrate wetting, 1312; tensile stress, 1312; thicknesses, 1311
- Thermal expansion: α - β transition of quartz, 1312; coating-substrate matching conditions, 1309; prediction with Seger coefficients, 1312
- Elaboration
- Coloration: bulk, 677, 1316; Cu⁰ nanoparticles, 1320; gilding (Au) and silvering (Ag), 1319; pigments, ancient, 1318–19; modern, 1318
- Fabrication: aqueous slurry, 1311; composition adjustments, empirical, 1313, on structure-composition relationships, 1313–15; mineral precursors, 1311; purification, 1311
- Firing conditions, *Grand feu*, 1312; *Petit feu*, 1312; Seger checking reference cones, 1313
- Enamels
- on glass: ancient artifacts, 1321; stained glass, 1320
- on metals, 1320: chemical compositions, 1321; *Grisaille*, 1321, 1350; reaction with oxidized metal surface, 636, 1315
- Glazes
- Compositions: chemical and mineralogical of modern porcelain glaze, 1313, 1314; chemical of ancient glaze on terracota, stoneware and porcelains, 1323

Glazes and enamels (*cont'd*)

Production: ancient, 1322; Chinese, 1322; European imitations, 1322; Japan, 1324; Islamic imitations, 1322; Ottoman empire, 1323

Products: celadon, 1309; *champlevé*, 1309, 1320; *cloisonné*, 1309, 1320; Graufesenque *sigillata*, 1322; grisaille, 1321; Han to Sui potteries, 1322; Raku, 1234; Shang and Shang-Zhou dynasties, 1309; Tang porcelains, 1322; Venetian, 1310, 1332, 1334, Yuan porcelains, 1322

Glazing for cars (and transportation means), 1091

Constraints: acoustic comfort (sound-transmission loss) 1095; design integration, 1094; information display, 1096; recycling, 1096; safety, 1093; scratch resistance, 1093; 1095; thermal comfort (solar-heat transmission), 1095; vision, 1092; windshield defrosting, 1093

Manufacturing: cutting, 1097; final operations, heating, 1097; forming and strengthening of laminated parts, 1100; strengthening of tempered parts, 1097–1100; screen printing, 1097

Glazing in buildings, *see* Structural glass in architecture

Gob: 1363, 1380

Graham's salt, (NaPO₃)₆: 901, 903, 1424

Greek views on glass, 1275

Connection with alchemy: *Art imitating nature*: Bolus of Mendes, 1278, 1280; connection with gold and gems, 1279; glassware, 1282, 1396; stone counterfeiting, 1278, 1280 Theophrastus views, 1277; transmission to Byzantium, 1280

Philosopher's speculations: Aristotle exhalation theory, 1276; Empedocles theory of pores, 1275; *hyalos*, 1275; Plato theory of water and fire mixture, 1276

Guardian company: float-glass strategy, 1141

H

Hardness, 382

Heat capacity, *see* Thermodynamic properties

HF etching, 393, 758, 1425

Horror vacui, 1399, 1409

Hyalos: 1275, 1276

Hybrid inorganic-organic polymers, 1057

Background: advantages, 1057, 1060; inorganic/organic property adjustment, 1061; physical properties, 1061

Sol-gel synthesis: polymerization steps, 1060; two-photon induced polymerization, 1066; type I-IV precursors, 1058

Structure; 1057

Uses

Bulk materials, fibers and composites, 1065–66

Coatings: 1061; 1062; on glass (e.g. for preservation of cultural heritage), 1062; on metals and polymers, 1064

Nanoparticles, 1065

Hyperquenched glasses, 349

Main features: boson peak, 354; fictive temperatures, 349; mechanical properties, 355; structural heterogeneities, 356

Relaxation: Johari-Goldstein on rigid molecules, 354; secondary, 351

I

Ice, *see* Amorphous ice

Immobilization of municipal and industrial waste, 1191

Environmental considerations: alteration of glass

particles and mineral precipitation, 1199; landfilling, 1200–03; pollutant emissions, 1191; residue leachability and changing mineralogy, 1199; residue reuse, 1200

Incineration plants: calorific value of waste, 1192; dry-discharge technology, 1198; flue-gas production, 1191; operating principles, 1192; pyrolysis and gasification, 1198; residue classification, 1192

Residues, 1191

Air-pollution control (APC): compositions, 1194; removal, 1198

Bottom ash: chemical compositions, 1193–95; glass phase, 1195, 1196; heterogeneity, 1069, 1193; mineralogy, 1195

Fly ash: composition, 1197; mineralogy, 1197

Special: coal combustion, 1201; sewage and dredging sludges, 1202; special and hazardous waste, 1202

Immobilization of radioactive waste

Background: amount of spent fuel, 1206; composition of fission products, 1208; history, 1205; new projects, 1216; plant operations, 1207, 1215

Existing facilities: Belgium, 1216; France, 1214; Germany, 1216; Japan, 1216; India, 1216; Russia, 1216; U.K., 1215; U.S.A., 1215

Industrial implementation: continuous process, 1213; two-step process, 1213

Long-term glass stability: chemical durability, 1210; self irradiation, 1212; storage context, 1209; thermal stability, 1212

Nuclear glasses: chemical compositions, 1209; formulation criteria, 1206; phosphates, 1208; physical properties, R7T7, 1210; required containment properties, 1208; selected borosilicates, 1208

Impact glasses, *see* Extraterrestrial glasses and Geological glasses

Incandescent lamps, 776

Indium tin oxide (ITO), transparent conducting films:

fabrication, 769; uses in LEDs and OLEDs, 783, in screens, 792, 794; thin films, 977

Intermediator effect, electrochemistry, 613

International Commission on Glass (ICG), 1219

Main features: foundation, 1219; logo, 1221; membership, 1223; member countries, 1225

- Organization: funding, 1221; goals, and management 1219; presidents and vice-presidents, 1221; treasurers and executive secretaries, 1222
- Prizes awarded: Gottardi, 1228; President's, 1229; Turner, 1229; Weyl, 1227
- Public activities: congresses and conferences, 1223–24; 1227; publications, 1226; Summer and Winter schools, 1224–26; web pages, 1221
- Technical activities: committees, 1222; 1224; coordination, 1222
- Ionic radii, table of, 20
- Ionic transport, 453
- General; applications, 562; discovery, 453; fast ionic glasses, 462; measurements 454
- Mechanisms
- Glass: vacancy (Anderson-Stuart), 456; dynamic structure, 456; interstitial pair (Charles), 456, 457, 466; insights from diffusion data, 456; weak electrolyte, 458
- Liquid: additional contributions, 458; role of configurational entropy, 458
- Variations with: composition, 455; pressure, 45; temperature, 454
- Ion “stuffing,” *see* Strengthening, chemical
- Iron
- Miscellaneous: Fe^{2+} chemical analyses, 523; maximum content according to glass types, 55; optical basicity, 600; partial molar volume of oxides, 306; role in basalt corrosion, 833
- Optical properties: Fe^{2+} and Fe^{3+} optical absorption coefficients, 681; glass coloration, 683, 686, 688; infrared absorbance, 1098
- Raw materials: hematite and magnetite, 43; maximum impurity content, 49
- Redox: equilibrium, 61, 104, 203, 597; kinetics, 586; potentials, 623; states, 203
- Structure: coordination and redox state, 155; structural roles, 204; structure-property relationships, 205
- Islamic glass
- Glassmaking: al-Birûnî's description, 1418; Beth Eli'ezer Roman-type furnace, 1262; cullet recycling, 1330; ninth-century decline of natron-type glass, 1270, 1417; opacifier spread, 1322; redox luster, 1319
- Optical researches: al-Haytham, 1388
- Products: enameled Mamluk mosque lamps, 1321, 1332; gilded and silvered mosaics, 1331; glassware for alchemy, 1396; lapis-lazuli blue glass, 1333; imitation of Chinese glaze, 1322; Ottoman glaze, 1323
- J**
- Jena apparatus glass*, 867
- K**
- Kauzmann paradox: definition, 16, 284, 567, 1431; perfect glass, 375; relevance to glass formation, 257; temperature, 266, 275;
- Kieselguhr*, diatomite, 956
- L**
- Lacrymae batavicae*, *see* Prince Rupert's drops
- Laminating: beginnings, 1074; of bended glass, 1085; history, 1091; polyvinyl-butylal (PVB), 1074, 1092
- Laser glasses: background, 697, 702, 707, 709, 735; fiber, 726; mid-infrared, 739; phosphate, 909
- Lattimo*, Venetian, 1333, 1335
- Lead-bearing silicate glasses, *see also* Flint glass
- Chemistry: composition, 28; durability, 641, 642; lead-leaching characterization, 524; lead-leaching coating protection, 1063; oxygen species, 156
- Crystal glass; making in Venice, 1329; Neri's mention, 1364; seventeenth-century patents, 1338, 1394
- Industry: challenging Pb replacement, 32; making in recuperative furnace, 1151; recycling problems, 1186
- Lead isotopes: for provenancing of ancient glass, 1257
- Leblanc process for Na_2CO_3 synthesis, 1420
- Light-emitting diodes (LED): display panels, 795; lighting, 782
- Lighting, 775
- Ancient lamps: combustion, 775; electric arc, 775; Yablochkov *candle*, 776
- Chemical compositions and properties of modern glasses, 777
- Electric discharge lamps: fluorescent, 780; glass constraints, 780; high-intensity discharge, 780; Ultra-violet, 780; Xenon, 781
- Incandescent lamps: black-body emission, 776; glass constraints, 778; traditional, 777; tungsten-halogen, 779
- Solid-state diodes: energy efficiency, 781; light-emitting (LEDs), 782; quantum-dots, 782; organic light-emitting (OLEDs), 783
- Liquid-crystal display panels, 793
- Liquid-liquid unmixing
- General features: bypassed in sol-gel syntheses, 974; depressing effect of Al, 641, 708; discovery, 1425; Dietzel field strength criterion, 255, 1432; nucleation in glass-ceramics, 942; subliquidus, 537; thermodynamics, 532, 539
- In: ancient glass, 1318; binary SiO_2 -metal oxides, 532; CaO-SiO_2 , 549; metallic glasses, 924; $\text{Na}_2\text{O-B}_2\text{O}_3\text{-SiO}_2$, 33, 868
- Liquidus temperatures, 31
- Lubbers process for flat glass, 67–68
- Lunar glasses, *see* extraterrestrial glasses

Maxwell model: relaxation, 13, 331, 1431; relaxation time, 250, 339

Mechanical properties, 379

Empirical calculation of Young's modulus and Poisson ratio for glasses, 30, 34

Flaws: coating filling, 389; size, 395; statistics, 386; surface flaws, elimination, 393

Fracture: annealed glass, 1076; conchoidal, 383, 824; crack generation and propagation, 382, 384; glass beam, 1078; laminated glass, 1094; stress corrosion, 38; tempered glass, 388, 1076, 1094; toughness and strength, 383; Vickers indentation, 382; Weibull plots, 386, 1074

Moduli and hardness: elastic moduli, 380; plasticity, 382; Poisson ratio, 34, 381; Young's modulus, 34, 381; temperature dependence, 381; tensile strength, flat glass, 393

Of: dental glass-ceramics, 1006; diatom frustules, 960; glass families, 384; glass-ceramics, 943; hyperquenched glasses, 355; irradiated glasses, 411; main glass families, 384; metallic glasses, 381; oxide glasses, 381; reinforcement fibers 98; sponge spicules, 958

Memory glass effects, 373

Mesopotamia

Artifacts: blue lump, late 3rd millennium, 1249, 1250; bottle, 1252; glazed items, early 2nd millennium, 1309; king Nabonidus' collection, 1441; making of synthetic basalt, 1415

Technology: glass furnaces, 1415; glass melting, 1415; viscosity estimates, 431, 1415

Views on glass, 1273

Metal-glass interactions, 629

Interface phenomena

Chemical interactions: effects of glass basicity, 631; oxygen pressure, 631; redox potential, 631; temperature, 631

Stability of redox species: electroactivity domain, 631; oxide solution in metals, 631; reaction pathways, 632; surface layers, 631–33

Wetting and adhesion: detachment temperature, 630; effects of atmosphere and composition; of metal surface oxidation, 631; modified sessile-drop measurements, 630

Metal-glass interactions

Characterization: corrosion potential and polarization resistance, 634; electrochemical impedance spectroscopy,

625, 635; linear voltammetry, 634; raw immersion technique, 633

Reactions of corrosion

Alloys: Al-forming, 636; Cr-forming, 636; molds for container fabrication, 83

Pure metals: common, 636; noble, 635

Temperature effects, 637

Metallic glasses, bulk, 919

Glass formation: chemical compositions, 920, 927; critical cooling rates, 251; density criterion, 920; discovery, 919, 1434, 1457; viscosity criterion, 922; vitrification vs crystallization, 921

Magnetism: soft materials, 931; hard, 932

Mechanical properties: dynamic, 929; fatigue, 927; fracture toughness, 926; friction and wear resistance, 926; low-temperature, 927; quasi-static room-temperature, 926; strain-rate sensitivity, 930

Miscellaneous: glass transition, 921; Johari-Goldstein relaxation, 355; polyamorphism, 368

Physical properties: elastic moduli, 381; low-frequency vibrational modes, 297; thermal and electrical conductivity, 922

Room-temperature deformation

Shear: deformation bands, 928; softening, 928; transformation zones, 927;

Transformations: glassy-crystal alloys with transformation-induced plasticity, 930; mechanical behavior of glass-crystal composites, 930

Structure: dense packing of hard spheres, 189; 191; heterogeneities, 924; partially crystallized, quasicrystals, 925; phase-separated glasses, 924; porous glasses, 925; short-range order, 923

Uses: catalysts, 934; chemical vessels, 934; flow meters, 932; medical, 934; molds, 932, 933; motor parts, 932; sensors, 932; shot-penning balls, 932

Metallurgical slags, 843

General: aluminum, copper, iron metallurgies, 844; blast furnace, 843; compositions, 846; cryolite, 843; functions, 844; world production, 843

Problems: refractory erosion, 845; slag droplet entrapment, 844

Properties

Chemical: *docile/hostile* reactivity, 847; kinetic control, 844; optical basicity, 600; phosphorus capacity, 854; sulfur capacity, 853

Physical: density, 853; structure, 848; surface tension, 854; thermal expansion, 853; thermodynamic, 853

Transport: diffusion coefficients, 851; electrical conductivity, 850; thermal conductivity, 852; viscosity, 849

Metal, molten glass: 1362, 1369–70, 1416

Meteorites, *see* Extraterrestrial glasses

Microscope, 1392, 1393, 1394

Microsegregation in network glasses, 193

Mineral wools, 1103

General: chemical compositions, 1104; classification: glass and stone wool, 1104; industrial, natural and recycled raw materials, 1104

Physical properties: crystallization tendency, 1107; fictive temperature, 1108; high-temperature stability, 1108–09; mechanical properties, 1109–10; viscosity, 1106–08

Properties: anomalous relaxation, 352–54; biopersistence and biodurability, 1110–11; chemical durability, 642; thermal conductivity, 1103

Spinning technologies: cascade spinning, 1105; rotary spinning and TEL process, 1105–1106; spinnability, 1106–08

Mixed-alkali effect

Channel, 193

Effects on physical properties: diffusivity, 471; electrical conductivity, 472; ionic conductivity, 455, 456

Structural considerations: 193, 508

Use in bioglass, 993

Mössbauer spectroscopy, 155

Municipal waste, *see* Immobilization of

Murano, 1328

Museums, 1441

Beginnings, 1442

Collection types: archeological, 1446; cultural history, 1443; decorative arts, 1443, 1444, 1445; princely, 1443; regional or specialized, 1448; scientific and technical, 1447, 1448–1449

Concerns and purposes, 1444, 1451

Corning, 1450, 1452

Forerunners: British museum, 1441; *Cabinets of art and wonders*, 1441; Japan, 1441; Musée français, 1442; Mesopotamia, 1441; National museums, 1442

International repertory of glass museums and glass collections, 1443

Pieces reproduced from: Archeological, Split, 1294; del Belrigardo, Ferrari, 1277; British museum, London, 1250, 1251, 1252, 1266, 1299, 1300; Centre international du Vitrail, Chartres, 1351, 1357; Cité de la céramique, Sèvres, 1310, 1311, 1317; Galileo, Florence, 1391, 1400; Glassmuseum Hentrich, Dusseldorf, 1231, 1445, 1453; Römisch-Germanische, Köln, 1301; du Verre, Conches, 1356; del Vetro, Murano, 1334, 1335, 1336, Victoria and Albert, London, 1268

N

Natron, trona: composition, 1262, 1343, 1415; flux for glassmaking, 4, 42, 48, 1261; Pliny's account, 1232, 1235;

Roman glass, 1261; ninth-century shortage, 1270, 1417; Venetian glass, 1329; Wadi Natrun exploitation, 1254, 1261, 1345

NBO/T: definition, 197, 201; determination, 187; influence on: diffusivities, 470; viscosity, 443

Nernst-Einstein equation, 454, 467

Neutron diffraction, 143–47

Nickel sulfide defect, 48, 398

Nonex, 868, 1424

NOx emissions: 63, 1161–63, 1175

Nuclear Magnetic Resonance (NMR) spectroscopy, 149

O

Obsidian, 823, 1237

Ancient uses: arrowheads, 3, 1240; biface and Levallois knapping, 2–3; blades, 3, 1240; cores, 1, 1240; miscellaneous, 1238

Archeological analyses

Chemical: summary of techniques, 1242; X-ray fluorescence, 1242, 1243

Dating: artifact wear, 1241; fission track, 405, 1242; hydration, 1241; radioactive, 1242

Geology: chemical compositions, 816; classification, 1238; conchoidal fracture, 824, 1238; European sources, 1243; trace-element compositions, 825, 1244

History: early melting observations, 1416; inship with manmade glasses, 1416

Properties: thermal conductivity, 496; viscosity, 444

Western Mediterranean artifacts: early Neolithic frequencies, 1245; implications for ancient trade and socioeconomic systems, 1245; sites, 1246; sources, 1244

Opacification

Agents: antimony, 1258, 1266, 1322, 1331; ground quartz grains, 1323, 1331; tin, 1267, 1334

In: first manmade glasses, 1254; Venetian glass, 1330–31, 1334

Phase separation mechanisms: liquid unmixing, 1318; partial crystallization, 1318,

Optical basicity, 597

Basics: basicity scale, 597, Lewis acids and bases, 597; transition metals as basicity probes, 598

Electron transfer: d-d absorption spectra, 598; s-p spectra, 598; Racah number, 598

Optical basicity: definition with Pb^{2+} probe ion: 599; dependence on composition, 599; high- and low-basicity materials, 604; relationship with electronegativity, 604; with onset of metallic bonding, 606

Uses: electrical polarizability, 601–02; redox equilibria, 600; structure and bonding changes through chemical reactions, 601

Optical fibers, 705, 721

Beginnings: luminous fountains, 705; first crown-glass fibers, 705; total internal reflection, 705

Optical fibers (*cont'd*)

Design: core-clad, 710; double-clad, 711; microstructured and photonic crystals, 711

Fabrication: chemical vapor deposition, 715-716, 764; melt quenching, 715

Fiber production: direct from double crucible, 717; drawing from core-clad preform, 717; protective coating deposition, 389, 710, 717

Glasses

Physical properties, 712

Transmission in infrared: chalcogenides, 714; fluorides, 713; germanates, 713, tellurites, 713

Transmission in visible: phosphates, 712; silica, 711; silicates (bearing Al_2O_3 , B_2O_3 , F, GeO_2 , GeO_2), 711

Optical uses

Active: amplification, 708; doping with rare earths, 707; fluoride glasses, 725; influences of glass composition, 708, and dopant concentration, 708; optical lasing, 707, 714; photoluminescence devices, 701

Nonlinear: frequency-mixing processes, 709; multiphoton absorption, 709; stimulated Raman and Brillouin scattering, 709

Passive: absorption, attenuation, dispersion and scattering, 706-07; dosimeters, Ce-doped, 412; ultra high-pressure and temperature science, plasma-induced catastrophe, 1458

Optical glasses, 665

Light: electromagnetic radiation, 665; velocity, 667; white: 666, 1387

Light-glass interactions: absorption, 669, 671; reflection, 666, 671; refraction, 667, 1388, 1389; transparency, influence of atomic weight and bond strength on infrared, 722

Optical components: filters, 674; lasers, 697, 702, 726, 739, 909, lenses, 673; mirrors, 674; prisms and gratings, 674

Organic polymers, 675

Refractive index

Basics: composition dependence, 672; constancy in glass, 675; Snell-Descartes law: 667, 1391; wavelength dependence, 667

Dispersion: Abbe number, 667; chromatic aberration, 667, 673

Glass properties: Abbe diagrams, 668; bonding, 670; homogeneity, 671; types, 672

Optoelectronics, 735

Chalcogenide active glasses: doping with trivalent rare-earth ions, 735; effect of local structure, 739; influence of dopant concentration on radiative lifetime, 738

Mid-infrared lasers: background, 739; Dy^{3+} -doped chalcogenides, 740; Pr^{3+} -doped chalcogenides, 741

Optical fiber amplifiers in telecommunication windows:

O-band (1260-1360 nm), Dy^{3+} and Pr^{3+} , 736; S-band (1460-1530 nm), Tm^{3+} , 736; U-band (1625-1675 nm), Ho^{3+} , 737; rates and temperature dependence of multiphonon relaxation, 738

Quantum dots

Basics: conduction and valence bands, 743; effective band gap, 743; 743; optical properties, 744

Fabrication: ion implantation and annealing, 746; nucleation and growth from precursor glass, 744; sol-gel methods, 745

Matrices: phosphates and silicates, 745-46; processability and durability, 745

Uses: amplifiers in fiber-optics communication, 747: coloration in Art Nouveau yellow enamels, 747, 1322; mid-infrared gain media, 748

Order parameter, 229, 267, 275, 1431

Organic light-emitting diodes (OLED) display panels, 794

ORMOCER (organically modified ceramics), 1057

ORMOSILS (organically modified silicates), 973

Oxynitride glasses, 891

General: fracture, strength, 897; glass ceramics, 898; glass formation, 892; nitrogen solubility, 891; phosphorus oxynitrides, 899

Physical properties: mechanical and elastic, 896; optical and electrical, 898; rheological, 896; summary, 895; thermal, 896; vibrational density of states, 895; volume, 896

Possible applications, 899

Structure: Al incorporation, 893; N-Al bonding, 894; N-Si bonding, 893

P

Palagonite, 831, 839

Parison, 1298

Peep hole, 1154

Pelé's hair, 821

Perlite, 825, 1238

Permanent compaction, 16, 875, 1430

Pharmaceutical glasses, 879

Basics: container types: 89; fabrication (Danner and Vello processes), 881; markets, 880

Chemical resistance: corrosion reactions, 883; extractable substances, 884; hydrolytic testing, 884; pH neutrality, 883

Physical resistance, 882

Surface problems: delamination, 885; particle release, 887; tungsten release, 886

Treatments: ammonium sulfate spraying, 887; chemical strengthening, 388, 888; surface siliconization, 887

Phase-change materials, 462, 1459

Phase equilibria, 529, 545

Basics: binodal, 532; critical point (temperature), 33, 360; 541, 572; equilibrium criteria, 531; eutectic, 533; Gibbs free energy of mixing, 531; liquidus, 536; peritectic, 534; phase rule, 531, 1425; solidus, 536; spinodal, 532; solvus, 536

Phase diagrams,, 32, 541–42

Topology

Binary diagrams with solid solutions: complete, 533; nonexistent, 533; partial, 536; SiO₂-metal oxides, 539–41

Ternary diagrams, 537; borosilicates, 541; CaO-Al₂O₃-SiO₂, 32; Na₂O-B₂O₃-SiO₂, 33, 541, 868; Na₂O-CaO-SiO₂, 32, 541–42

Phase rule, 531, 1425

Phase transitions, *see* Amorphous ice, Crystal nucleation and growth, Polymorphism

Philosophical egg, 1396

Phosphate glasses, 901

General: chemical compositions, 904, 907; Graham salt, (NaPO₃)₆, 901; *inorganic* polymers, 902; synthesis, 904

Properties

Chemical: corrosivity, 905; dissolution in aqueous solutions, 912; interactions with silicates, 603; ion release, 912

Optical: Abbe diagram, 909; rare earth doping, 908

Physical: Arrhenius parameters for diffusion in, 469; viscosity, 906, 908; volume, 906

Structure

Chain structure: chain length, 903; composition effect, 903; nomenclature (ortho-, pyro- and metaphosphate), 902; phosphate groups, 902

Mixed networks: aluminophosphates, 903; borophosphates, 903; phosphorus oxynitrides, 899; silicophosphates, 903

Uses

Biologically related: boluses in veterinary medicine, 1001; fertilizers, 901; food industry, 913; medicine, 915

Mineral: metal lubricants 914; mineral analyses, 901, 914; nuclear waste containment, 901, 1208; seals, 914; water softening, 901

Optical: high-power solid-state lasers, 909; infrared optical fibers, 712, 910; LED lighting, 911; phosphors, 910; quantum-dot matrix, 746; spectral filters, 908

Physical: capacitors, 914; dielectrics, etc., 901; electromagnetic dosimeters; 911

Phosphors: common, 782, 910; composition and light emission, 911

Phosphorus

Elemental P: discovery, 901; liquid-liquid transition, 368

In oxides: effect on radiation-induced attenuation, 407; incorporation in oxynitride glasses, 899; LIPON glass

electrolytes, 1126; optical basicity, 599; P capacity, slags, 854; PO₄ tetrahedron, network former, 176; presence in waste, 1202; Si,P substitution, 205

Phosphosilicate glasses: bioactive glasses, 978, 991, 998; existence of 6-fold coordinated Si, 136; optical fibers, 712

Photoluminescence, 693, 694

Background: inelastic light scattering, 694, 695; photoluminescence schemes, 695–96; quantum efficiency, lifetime and quenching effects, 700; radiative and non-radiative relaxation, 701; upconversion processes, 695

Electron configurations: excited states of bismuth ion species, 699; rare earths and transition metals, 695; trivalent rare earths, 698

Glass chemistry: critical dopant concentration, 700; effects of matrix composition on ligand configuration and phonon energy, 697; emission example of Eu³⁺-doped glasses, 696; influence of redox state, 698; sensitization through codoping, 697

Uses

Laser glasses: lasing species and sensitizer-activator combinations according to glass type, 702; Nd³⁺ commercial products: LG 660, LG 670, LG 680, LSG 91H, Q246, 702, 909

Optically active fiber devices: Er³⁺-doped fiber amplifiers (EDFA), 699; other devices, 701.

Tin side identification of float glass, 693

Physical constants, 21

Phytoliths

General: discovery, 957; ecological importance, 955; morphology, 959; physiological role, 955, 961; silica synthesis, 963; soluble silica uptake from soil, 963; water solubility, 961

Uses: archaeological and paleontological research, 957; rice hull ashes, 961; silica nanoparticles, 961; water glass synthesis, 859

Pigments, 1316

Colorants: chemical compositions, mineralogy and crystal structure: ancient, 1319; compositions, and crystal structure, modern, 1319; electronic transitions, 1316

Coloring mechanisms: crystal-field transitions, 1318; nanoparticles, 594, 690, 1318; opacification by partial crystallization or liquid unmixing, 1318; light diffraction, 1319

Pilkington Brothers: AR reinforcement fibers, 97; float process design, 72, 74, licensing to other companies, 73, 1140; purchase by NSG, 1143; regenerative tank furnaces, 1369; twin grinder for plate glass, 71, 1375

Pitchstone, 825

Pittsburgh Pennvernion updraw processes for flat glass, 71

Plastic crystals: glass transition, 12; relaxation, 1026

Plasticity, 382

Plastics, *see* Polymer glasses

Plate glass

Continuous casting: Bicheroux process, 1374; continuous grinding and polishing, 1375, 1376; undesired hue with Gehlen soda ash, 1420

Nineteenth-century expanding market, 1373; price evolution, 1806–1878, 1374; production with the float process, 1375

Saint-Gobain process: annealing in *carcaises*, 1372; casting, 1372; grinding, 1372; polishing, 1372

Venice products, 1337, 1372

Plexiglas, 1031

Polishing

Processes: acid etching, 642; air abrasion, 1000; flame, 394, 753; fluid-jet, 394; ion-beam technologies, 756, 757; mechanical, 393, 643, 1372, 1375

Product: plate glass, 71, 376, 1136, 1372, 1375, 1376

Roughness measurements, 168, 754

Theories: 757

Polyamorphism

In: amorphous ice, 365; BeF₂, 365; D-mannitol, 1458; Ge, 366; GeO₂, 365, metallic glasses, 368; Si, 366; SiO₂ glass, 362, 365; Y₂O₃-Al₂O₃, 367

Theoretical aspects: configurational energy landscape, 363; critical points, 366–67; liquid-liquid transitions, 359; link with pressure-induced amorphization, 365; melting curve maxima, 360; phase separation, 191

Polymer glasses, 1031, 1043

Chains: macromolecules, 1032; rotational isomers, 1033; skeletal rotations, 1032; stiffness, 1032

Glass transition: α transition, 1036, 1052; dependence on structure and composition, 1038, 1052–54; heat capacity change, 264; secondary transitions, 1037

Optical properties: Abbe diagram, 668; applications, 675

Physical aging, 1038

Polymerization: chain growth (thermoplastics), 1043–48; control, 1049; free-radical, 1046; industrial, 1050–52; step growth (thermosets), 1048–50

Products: fibers and films, 1039; foams, 1039; hollow fibers and porous membranes, 1039; transparent materials, 1039

Semicrystalline polymers, 1036, 1054

World production, 952

Polyvinyl-butylal (PVB), 1074, 1092

Pontil, 1296

Porcelain

General: ceramic products 1309, 1421, 1422; glaze compositions, 1313, 1323; hues, 1316, 1317; imitation of

Chinese ware, 1421; partial melting and Réaumur porcelain, 1422; *porcellano*, 1334

Miscellaneous: dental restoration, 1005; impurity in cullet, 1185

Portland vase, 1300

Pressure-induced amorphization, 371

Impact-produced glasses: lunar, 807; terrestrial, 817

In: AlPO₄, 373; Cu₂O, 373; ice, 371; SiO₂, 373; SnI₄, 373; zeolites, 375

Theoretical aspects: compositionally driven instability, 373; configurational energy landscape, 376; link with polyamorphism, 365; negative slope of metastable melting curve, 371

Prigogine-Defay ratio, 265

Prince Rupert's drops: discovery, 1420; Hooke's drawings of rupture patterns, 1420; internal stresses 245; rupture and etching experiments, 1425–1426

Prospects, 1123

Pseudotachylites, 820

Pumices, 822, 823

Pyrex, 868, 1395, 1424

Q

Qⁿ-speciation

General: definition, 135, 179, 201, determination from vibrational spectra, 151, 154; extension to aluminosilicates, 180, 202; phosphates, 902

Modifications upon: melting, 327; solution of CO₂, 575; N₂, 576; water, 574

Quantum dots, *see* Lighting and Optoelectronics

Quartz

Geology: accumulation as sand, 6; fulgurite source, 815; quantum-chemical origin, 6

Glassmaking

Coloration: opacifier, 1267, 1323, 1331; pigment, 1319

Component of: glass-ceramics, 940, 942, 944; fly ashes, 1197; soft paste porcelain, 1322

Melting: competition with cullet for Na₂CO₃, 59; digestion kinetics, 39, 45, 60–62; first melting and vitrification, 1422

Raw material: ancient and modern glasses, 5, 41, 858, 1235, 1258, 1261, 1311; grain size requirements, 40; impurities, 45

Properties: boson peak, 321; cristobalite formation, 315; hardness, 40; heat capacity, 289; phase transitions, 6; Raman spectrum, 293; soft mode, 296; structure, 132, 144, 149; vibrational entropy, 319; thermal expansion, 1312; water solubility, 860

Quench boxes, for glass tempering, 1098

R

Radiation effects, 405

- Agents and mechanisms: intrinsic and extrinsic parameters, 407; ionizing radiations, 408; nuclear collisions, 408; point defects
- Effects: bubble formation, 408; densification, 409; mechanical properties, 411; mitigation, 411; network-structure modifications 408; optical properties, 409
- In: aluminosilicate glasses, 411; minerals, 405; nuclear waste glass, 405; silica glass, 409

Radioactive waste, *see* Immobilization of

Radiolarians: Haeckel's morphological drawings, 951; model for the 1900 Paris world Fair entrance pavilion, 957; silica tests, 956, 964

Rare earth elements: diffusivities, 470; electrochemical effects, 613; electron configurations, 695; excited-state configurations of trivalent species, 698; phosphors, 911; recycling from waste, 1203

Raw materials, 39, 54

- General: correlation hardness-melting temperature, 40; hygroscopicity considerations, 40; mineral purification, 45; quantification of heavy minerals, 45
- Natural and synthetic materials: composition, mineralogy, origin and prices, 41–43
- Roles (colorant, fluxes, formers, modifiers, refiners, oxidizers, reducers, strengtheners), 40
- Special cases: boron, 49; cullet, 40, 44, 1179; *globetrotting* minerals, 49; iron-poor, 49; lithium, 49; sodium carbonate: natron, 48, Solvay process, 49
- Specifications: cost, 39; digestion kinetics, 45; grain size, 40; maximum iron contents according to glass types, 55; sieve particle-size distributions, 44, 61

Recycling, *see* cullet

Redox factors for batch fusion, 57

Redox reactions: equilibrium constants, 620; kinetics, 586; optical basicity, 600; standard potentials, 621; thermodynamics, 581, 619

Redox thermodynamics and kinetics, 581

- Basics: reference reactions, 581; Ellingham diagrams, 582, 583; equilibrium constants, 582; general redox reactions, 584; Gibbs free energies of reaction, 582, 584; industrial relevance, 585

Oxidation/reduction kinetics

- Closed system (internal) dynamics: evolution of redox potentials, 593; incorporation of carbon oxides under reducing conditions, 593; reduction of gold in ruby glasses, 594; solubility of Pt-group elements, 594; sodium sulfate fining, 595
- Open system dynamics: kinetic modes, 587; kinetically controlling diffusion of divalent cations, 587; oxide surface films, 588; polarons (electron holes), 589; redox

- reactions, 586; structural changes of iron, 587, structure-polymerization influence on oxidation, 589; relevance to float-process reducing conditions, 584, 591

Reinforcement fibers, 95

- Chemistry: composition and properties, 97, 98, 108; durability, 642

Development from E-glass, 95

- Fabrication: continuous fiber production (sketch), 101; forming, 103, furnace simulation, 119, 123; iron-redox control, 104, melting and fining, 102, *sizing* (binder coating), 104

Mechanical strength, 385, 1426

- Polymeric binders: classification of fibers from functionalities achieved, 105; interfacial shear stress, 105; organosilanes, 106

Production: main producers, 100; world markets and sectors, 106, 107

- Uses: AR-Glass (alkali resistant) 97; C-Glass (acid resistant), 96; D-Glass (electronic applications), 97; E-Glass (general reinforcement), 96, 869; R-Glass, 97 (wind mills and military); S-Glass (high-temperature), 99

Relaxation in molecular liquids, 1013

- Basics: correlation functions, 1013; depolarized light scattering, 1013; dynamic susceptibilities, 1013; primary α -relaxation, 1015; rotational degrees of freedom, 1013; their differing relaxation dynamics, 1013

- Dynamic susceptibilities: changes with temperature down to the glass transition, 1015; characteristic length scales, 1019; correlation with fragility, 1019; *dynamic* and *static* lengths, 1020; glass transition, 1016; insights from molecular dynamics simulations, 1019; non-Arrhenian time constants, 1015–18

Glass-forming liquid, binary systems: dynamical

- heterogeneities, 1021; implications for dual glass transitions and relaxation, 1022; observations for polymer blends, 1022–24

- Secondary relaxation: cooperative process, 1025; high-temperature merging of α and β -peaks, 1025; local origin of the process, 1025

- Systems of *plastic* or *glassy* crystals: calorimetric glass transition, 12; molecular rotations and restricted reorientations, 1026

Relaxation, structural and stress, 331

- Basics: kinetic equivalence, 13; Maxwell model, 339; phenomenological aspects, 7; relaxation times, 8, vibrational vs. configurational, 14, 334; temperature dependence, 342

- Experimental observations: anomalous relaxation, 352–54; heat capacity, 337; viscosity, 8, 444, 1431; volume, 303, 335

Models

Relaxation, structural and stress (*cont'd*)

- Adam-Gibbs, 275, 346, 433, 439, Tool, 334; 1430
- Tool-Narayanaswamy-Moynihan: background, 335; calorimetric parameters, 337; prediction of thermal shrinkage, 338; of refractive index, 338

Secondary

- in: hyperquenched glasses, 351, 353; molecular liquids, 1024; polymers, 1037
- Johari-Goldstein, 354–55; 1025

Viscoelasticity

- Bulk: fictive pressure, 346; large pressure changes, 346; small pressure changes, 344–46
- Models: Burger, 341; (Kelvin)-Voigt, 340; Kohlrausch (Williams-Watt), 342; Maxwell, 339, 1431
- Shear: Boltzmann superposition principle, 342, 1431; compliance, 340; kinetic parameters, 343; Kohlrausch relaxation kinetics, 335, 342; 1431; shear relaxation in glass, 340

Reticella vessels, 1292

Reticulite, 821

Rock wool, *see* Mineral wools

Roll-out process, for wired and textured flat glass, 71, 1370

Roman glass, *see* Ancient glass

Rouge, iron oxide for polishing, 1372

S

Saint-Gobain, Compagnie de, 1140

- History: hiring of Italian glassmakers, 1372; merging with the Manufacture royale des glaces, 1372; wage increases in the 19th century, 1382

- Technology: fuel-consumption savings, 1368; installation of tank furnaces, 1368; plate-glass process, 1372–74; TEL process for glass wool, 1105; tempered glass, 1092

Salicornia (*Salsola soda*), 1254, 1420

Scanning Electron Microscopy (SEM): chemical analyses, 161–62; image formation, 160–61

Schott AG: automotive antireflecting coatings, 969; borosilicate laboratory ware, 441, 867, 868; dielectric metal thin film for narrow-band interference filters, 763; GlasMuseum, 1447; optical glasses, 867; optical phosphate glasses, 908; sol-gel products, 969; transparent glass-ceramics, 938

Screens and displays, 787

- Cathode-ray tubes: cathode rays, 789, 1406; chemical compositions for color tubes, 790; television, 789; X-ray absorption constraints, 789–90

Flat-Panel Displays

- Basics: device configurations, 788, 790, 795; drivers for thin-film transistors, 792; front covers, 792; market growth, 787; maximum size, 788

Flat-Panel Displays Glasses: chemical compositions, 792; frits, 792; high strain-point values, 791; physical properties and strain points, 793, 795; thermal-compaction problem, 791

Liquid-crystal display panels: liquid crystals, 793; panel assembly, 794

Organic light-emitting diodes (OLED), 795

Plasma-display panels, 794

Transparent conducting oxides, 768, 783

Selenium: amorphous phase, 1414; component of chalcogenide glasses, 138, 714, 721; existence as chains in chalcogenides, 213, 727; glass transition temperature, 274; Kauzmann catastrophe, 16; phonon dispersion, 291; thin films, 733; use in animal bolus, 913

Separator substance, for ancient molding, 1287

Shear thinning, 432, 445

Sideromelane, 821

Silanol groups: aerogel synthesis, 984–85; biogenic silica condensation, 962; bioglasses, 994, 996; corrosion reactions, 640, 752, 861, 964; hybrid inorganic-organic polymers, 1062–63; sizing of reinforcement fibers, 105; sol-gel reactions, 971; surface component of Vycor, 871

Silica aerogels, 981

Fabrication: sol-gel chemistry, 982; solvent elimination, 981, 983; surface modifications and aging, 983

Properties: mechanical, 985; microstructure and porosity, mesopores, 983–84; summary, 982; surface chemistry, 984; thermal conductivity, 984

Silica hybrid aerogels, 988

Uses: growing interest, 982; main companies, 986, 987, markets, 986, 988; production, 986; spatial-dust collection, 986, 987; thermal insulation, 981, 986, 987

Silica, amorphous

Phases: biogenic, 995; fulgurites, 817, 818; polyamorphism, 362, 365, 426

Properties: Arrhenius parameters for diffusion, 468; boson peak, 189, 321; compressibility, 198; densification upon irradiation, 409; dispersion of acoustic phonons, 291; heat capacity, 289; light dispersion and attenuation, 707; thermal conductivity, 492; vibrational entropy, 319; vibrational spectrum, 239, 293; viscosity, 438; water solubility, 861, 962

Structure:

Experimental: first sharp diffraction peak, 132; neutron diffraction, 131–33; Raman spectroscopy, 153; XANES, 149; X-ray diffraction, 144

Outcome: Bell and Dean model, 131, 221; molecular dynamics simulation, 187; ring distribution, 228; Si coordination, 149; Si-O-Si angle distribution, 133, 198

Transformations: fiber drawing, 1422; nanoparticle formation from rice husks, 961; from water glass, 864; vitrification, 815

Uses: drug delivery with sol-gel nanoparticles, 993; glass vessels, 1399; optical fibers, 711; tungsten-halogen and xenon lamps, 779, 781; various, 27

 - Changing styles: early (Augsburg and Chartres cathedrals, Paris Sainte Chapelle), 1344, 1347, 1351; Renaissance (Paris Saint-Etienne du Mont, 1348, 1351); revival in 19th century: Christ church, Eccleston, 1355; Notre-Dame basilica, Bonsecours, 1354
 - Chemical compositions: in Belgium, 1346; England, 1345; medieval, 1345; plant soda ash, 1345; variability, 1345
 - Context: architectural improvements, 1347; Black Death interruption, 1347; glaziers' independence, 1347; religious purposes, 1346, 1347, 1348; Theophilus' descriptions, 1344
 - Decoration
 - Body coloration/decoloration: Co^{2+} blue, 1348; Cu^+ green or blue, 1349; Fe^{2+} , Fe^{3+} complex hues; Mn^{3+} purple; MnO_2 , glassmaker's soap, 1349; quantum dots, 747; solarization, 1349
 - Casing/flashing: Cu^0 nanoparticles, 690, 1349, 1350; redox mechanism, 1349
 - Enamels, 1350, 1351

- Stained glass windows (*cont'd*)
 Etching, 1350, 1355
 Painting: *grisaille*, 1350, 1351, 1352
 Silver staining: chemical recipe, 1351; yellow formation reaction, 1352
 Leading: aesthetic interest, 1352, 1353; *comes*, 1353; cutting, 1353; *ferramenta*, 1354; lead, practical advantages, 1353
 Modern
 Masters, 1355–57
 Styles: 19th–20th centuries: *Art nouveau*, 1355; *Arts and Crafts*, 1354; *dalles de verre*, 1355; Gothic revival, 1355; *pâte de verre*, 1357; Tiffany's innovations, 1355
 Restoration and conservation: 19th-century efforts, 1354; 1356; modern methods, 1353; provenance analyses, 1357, 1358
 Stokes-Einstein equation: uses, 263, 467, 562; breakdown, 433, 1018
 Stone wool, *see* Mineral wools
 Strain point, 29, 434
 Strengthening, 391
 Chemical strengthening: basics, 388, 756; differential-expansion, 401; ion-exchange diffusion, 399; ion “stuffing,” 399; physical parameters, comparisons with thermal strengthening, 392; stress profiles, 400, 1075
 Coatings: basics, 401; chemical-vapor deposited, 91, 402; flaw-fillings, 389; sol-gel, 402
 Flaw elimination: HF etching, 393; flame polishing, 394, 753; laser heating and cutting, 394; mechanical polishing, 393, 1072
 Limitations, 397
 Thermal strengthening: basics, 331, 388, 395, 756, 1075; compressive stresses, 395; Ni sulfide weakness, 398; Prince Rupert's drops, 425–1426; residual stresses, 397; stress profiles, 396, 1075; tempering process, 396
 Structural and microstructural probes, 141, 159
 Derived information, 142
 Electrochemistry, 612
 Microscopy techniques: Atomic force, 169; Scanning Electron (SEM), 160, 525; Transmission Electron (TEM), 163–68, 632; X-ray, 170
 Scattering techniques: neutron diffraction, 143–47; X-ray diffraction, 143–47
 Spectroscopic techniques: Mössbauer, 155; Nuclear Magnetic Resonance (NMR), 149; Scanning probe, 168–70; Ultraviolet/visible, 156; X-ray: absorption, 14–49; X-ray photoelectron, 155–56
 Vibrational spectroscopies: Brillouin, 154; Infrared, 152; Raman, 152–54, 1433
 Structural glass in architecture, 1071
 Applications: beam-column, 1084; façades, 1072, 1086; foot bridge, 1073; full glass structure, 1072; hanging panels, 1073; roof beams, 1072, 1083; staircase, 1072; structural fins, 1073
 Connections, 1079
 Adhesive: adhesive point, 1083, 1086; adhesive linear, 1082; large-area bonds, 1083
 Mechanical: friction, 1081; point-fitting 1079–80; through-bolt point, 1081
 Miscellaneous: chemical strengthening, 1088; coatings, 977, 1078; cold bending, 1085; custom-cast, 1086; maximum sheet size, 1083; reinforcement with hybrid components, 1086; smart glass, 1088
 Processing: mechanical, 1077; safety issues, 1077; structural analysis, 1078
 Structure, 129, 173, 183, 197, 207
 Cation classification: conditional (intermediate) network formers, 20, 134–35; network-formers, 20, 133–35, 173, 178; network-modifiers, 20, 133–35, 175
 Network structure: degree of polymerization, NBO/T, 197, 201; depolymerization, 175; NBO/T calculation, 197
 Ordering: differences between oxide and metallic glasses, 189, 199, 201; direct observation, 189; extended-range order, 183; intermediate-range order: ring distributions, 137; length scales, 187; short-range order:
 Oxygens: bridging and nonbridging, 178–79; coordination numbers, 133–35; Q^n -species, 135, 179
 Structural heterogeneities: general features, 192; in hyperquenched glasses, 356; metallic glasses, 924
 Structure indicators: first sharp diffraction peak, 138, 186; radial distribution functions: experimental, 145; simulated, 226
 Theoretical aspects
 Models: microcrystalline, 133, 1429; random network, 130, 135, 191; random packing of hard spheres, 191; topological constraint theory, 207
 Simulations: first-principles, 233; Monte Carlo, 224; Molecular Dynamics, 225
 Sulfide glass electrolytes for all-solid-state batteries, 1125
 Background: advantages of sulfide glass electrolytes, 1125; battery redox reaction, 1225; energy density, 1125; ion electrode intercalation-deintercalation, 1225; Li^+ and Na^+ conductivities in oxides and sulfides, 1127; solid-solid electrolyte-electrode interfaces, 1226; thin-film batteries, 1120
 Sulfide basics
 Electrical conductivity: effects of composition, 1128; microstructure and partial crystallization, 1129; optimization, 1129
 Preparation: quenching method, 128; planetary ball-milling, 1128

- Properties: chemical stability, 1128; electrochemical window, 1130; formability, 1130, structural features: 1127; Young modulus, 1127
- Sulfide-electrolyte batteries
- Electrodes: graphite and LiCoO_2 -type materials, 1130; interfacial resistance, 1130
- Interfacial design: electrode-electrolyte contact, 1131; electrolyte surface coating, 1131; nanocomposite electrolytes, 1132; use of the supercooled liquid state
- Sulfur capacity, slags, 853
- Surface modifications, 751
- Cleaning: electric-discharge, 755; plasma, 755; scrubbing and polishing, 755; solvent immersion, 758; ultrasonic, 755; vacuum heating, 755; vacuum ultraviolet, 756
- Hot-end processes: dealkalization, 399, 401, 645, 752; flame polishing, 394, 753
- Strengthening: ion-exchange, 388, 756; thermal tempering, 388, 395, 756
- Surface topography: flatness/roughness, 757; grinding and polishing, 757
- Texturing and structuring: aluminum-induced texturing, 758, 759; electron-beam laser interference lithography, 758; molding and embossing, 758; wet-chemical etching, 758
- Uses: application fields, 760; biology, 761; microfluidics, 758; optics, 758, 761; ultrathin glasses, 760
- Surface protection: ammonium sulfate spraying, 887; dealkalization, 645; siliconization, 887
- Syria, 3rd millennium bead, 1249
- ## T
- Tektites, 819
- Telescope
- Astronomical observations, 389-1391
- Glass quality: defects, 1362, 1394; improvements, 1394, 1408

 - Theories and equations: Adam-Gibbs, 215, 276, 325, 439; Avramov-Milchev, 438; configuron-percolation, 253; free volume, 276; MYEGA, 215, 438, VFT, 8, 438, 1431
 - Vitreous* electricity, 4, 1404
 - Volatile solubility, 571

General: composition dependence, 573; critical point, 572; effect of oxygen fugacity, 575, 576; phase equilibria, 572; solubility comparisons, 572; temperature dependence, 572

Non-reactive solubility: nitrogen, 571; noble gases, 556, 579

Reactive solubility and dissolution mechanisms: CO_2 , 574; halogens, 577; hydrogen, 578; reduced carbon, 575; reduced nitrogen, 576, 891; sulfur, 57

Volume properties, 301

Basics: Birch-Murnaghan equation of state, 308; measurements, 302; relaxation, 303; thermodynamic implications, 309

Compressibility: adiabatic, 10, 304; configurational, 14; 264, 304; frequency dependence, 10; isothermal, 16, 308; of various glass-forming liquids, 1460

Effects of: fictive temperature, 9, 302, 333; structure, 307

Thermal expansion

Coefficients of: ceramics, 1312; glass for thin-film transistor substrates, 793; flat-display panels, 792; glass-ceramics, 941, 1007; lighting glasses, 777; metals, 1312; slags, 853

Empirical calculation for glasses, 34; liquids, 306; temperature dependence, 308

Volume: composition dependence, 305; empirical calculation for melts: 306, and slags, 853; relationship with thermal conductivity, 49

Vulcanization, 1036

Vycor glass, 33, 200, 868–871

W

Water, *see also* Amorphous ice

Chemistry: corrosion, 639, 647, 752, 884, 1211; dissociation reaction, 609; optical basicity, 604; phosphate degradation rates, 913; solubility and speciation in silicates, 573, 574; stress corrosion, 387; transmutation into *earth*, 1397; water glass, 857, 1419

Effect on: density, 307; diffusivities, 470; heat capacity, 323; thermal conductivity, 494; viscosity, 443, 827

Geology: corrosion of natural glasses, 831; exsolution from magma, 827; lunar, 806, 810; perlite formation, 1238

Glassmaking: addition to suppress dust formation, 57; evaporation before batch melting, 59, 102; raw-material hygroscopicity, 40; Venetian purification of soda ash, 1332, 1418; water gas, from coke, 1367

Philosophy: Plato's views, 1276; relationship with glass and metals, 1416

Physics: critical cooling rate for glass formation, 253; diffuse strong-fragile transition, 217; dynamics in molecular liquids, 1020; luminous fountain, 706; polyamorphism, 365, 415; refraction, 1388; strengthening, 401; structural difference between bulk and surface, 238; vapor pressure at high temperatures, 1403

Solar-energy applications: desalination, 1121; rooftop heaters, 1117; splitting, 1120

Syntheses: enamel slurry, 1311; phosphate glasses, 905; sol-gel, 970, 982, 993

Water glass, 857

Basics: chemical reactivity, 863; first syntheses: 857, 1423; lithium, potassium and sodium compositions, 857, 860; physical properties, 863; silica solubility, 860

Fabrication from: crystalline sodium silicates, 859; dissolution of alkali lyes, 859; glass synthesis and dissolution, 857–59

Structure: colloidal, 862; molecular, 861

Uses: alkaline buffers, 863; fire retardants, 857, 864; precursors for silica materials, 863, 986; reinforcement with silica nanoparticles, 864; sources of reactive silica, 864; xerogels, 864

Weibull plots, mechanical testing, 386, 1074

World productions: containers, 92, flat glass, 67, 1139; polymer glasses, 952; reinforcement fibers, 106–07; silicate glasses (total), 24; metallurgical slags, 843; water glass, 857

X

X-ray techniques

Absorption

Extended X-ray absorption fine structure (EXAFS), 147–49; X-ray absorption near-edge structure (XANES), 147–49

Diffraction, 143–47

Anomalous scattering, 146–47; diffraction images and patterns, 144; pair-distributions and radial distribution functions, 145

Fluorescence: basics, 517; energy-dispersive, 161, 518; portable energy-dispersive, 1243; wavelength-dispersive, 161, 518

Microscopy, 170

Photoelectron spectroscopy, 155–56

Z

Zaffre, cobalt blue, 1348

Name Index

N.B. *Glass, discovery, invention or experimental study of, etc.*, implicitly meant whenever a term seems to be missing

Italicized page numbers referring to pictures included

A

'Abbas Ibn Firnâs: alleged SiO₂ vitrification, 1422

Abbe, Ernst: novel optical glasses, 867, 1424

Adams, Leason H.: annealing of glass, 1430; high-temperature practical scale, 1425

Aenas of Gaza: glass and metal transmutations, 1278, 1281

Agricola, Georgius: *De Re Metallica*, 1362; glass furnaces, 1364–1365

Allut, Antoine: author of the glassmaking entry in the *Encyclopédie* of Diderot and D'Alembert, 1364

Amontons, Guillaume: gas thermometer, 1402; temperature effects on gas pressure, 1401

Antonio da Pisa: treatise on painting on glass, 1351

Appert, Léon: mechanical glassblowing, 1371; wired glass, 1371

Arago, François: water-vapor pressure measurements up to 30 atm, 1403

Aristotle of Stagira: element *qualities*, 1276; homogeneity of mixtures, 1419; *hyalos*, glass, 1276; philosophy of matter, 1273; Lavoisier's refutation of this philosophy, 1397; viscous liquids and viscoelasticity, 1416

Ashley, Howard: shaping mold for bottles, 1378

Avogadro, Amedeo: molecular hypothesis, 1421

B

Babinet, Jacques: optical fiber, 705

Bacon, Roger : anticipation of the microscope and telescope, 1389–90; glass shape key to refraction and optics, 1389

Baekeland, Leo: bakelite, 1031

Baird, John Logie: image broadcasting, 789

Baliani, Giovanni: air weight acting in siphons, 1400

Barovier, Angelo; *chalcidony* glass, 1335; *cristallo*, 1332; *lattimo*, 1323

Bastie, François Royer de la: tempered glass, 1092, 1136, 1426

Baumé, Antoine: definition of glass, 1414; need for glass annealing, 1414; thermometer intercalibration, 1399

Beckman, George: pH meter, 610

Bede the Venerable, account of glassmakers from Gaul in 7th-century England, 1346

Benedicus, Édouard: laminated glass, 1091

Bernal, John D.: configurational properties, 1430

Bernoulli, Jean: England *flint* monopoly, 1394

Berzelius, Jöns Jacob: discovery of selenium, 1414; glass blower himself, 1399; isolation of silica, 1421; polyphosphates, 901

Bessarion, Basileios, cardinal: transmission of the alchemical corpus, 1282

Bessemer, Henry: first float-process patent for flat glass, 72

Beyer: *glass-cord* musical instrument, 4

Bicheroux, Max: rolled-glass process, 1374

Bickerstaff, Kenneth: float process for flat glass, 72

Bievez, Désiré: flattening and annealing *lehr*, 1370

Binet, René: radiolarian pavilion, 1900 Paris World Fair, 957

Biringuccio, S. Vanoccio: alchemical roots of glassmaking, 1418; *Pirotechnia*, 1362; reverberatory furnace, 1366

al-Bîrûnî: glassmaking, 1418

Biscop, Benedict: fetching glassmakers from Gaul in 7th-century England, 1346
 Boetius, Hennig: melting furnace, 1381–1382
 Boltzmann, Ludwig: superposition principle, 1431
 Bolus of Mendes: earliest alchemist, 1278; influence on glassmaking, 1280
 Bontemps, Georges: Crystal Palace glazing, 1371; diversity of glass uses, 2; *Glass Maker's Guide*, 1364; interpretation of Pliny's account, 1222; right starting materials for glass pots, 1381; stained-glass renewal, 1334; stained glass repairs at Ste Chapelle, 1357
 Bose, Georg Matthias: electric shock and *philosophical heroism*, 4
 Böttger, Johann Friedrich, lapis-lazuli whitening of Meissen porcelain glaze, 1318
 Boucher, Claude: mechanical blowing for bottles, 1376–1377
 Boudin, Louis: electrofused-refractory tank, 1375
 Bowen, Norman L.: phase-equilibria determinations, 1425
 Boyle, Robert: at the origin of Neri's translation, 1363; springiness of the air, 1401–1402; transmutation of water into earth in glass vessels, 1397; vacuum experiments, 1401
 Brand, Hennig: phosphorus, 901
 Braun, Karl Ferdinand: oscilloscope, 789
 Briati, Giuseppe: potash crystal glass, 1337
 Bridgman, Percy W.: permanent compaction of glass, 1430
 Brocard, Philippe-Joseph, modern enamel on glass, 1322
 Brunoro: Venetian glass recipes, 1328
 Buffon, Georges-Louis Leclerc, count of: igneous origin of the Earth, 1425

C

Carnegie, Andrew: founder of the Geophysical Laboratory, 1425
 Cellini, Benvenuto: enamels, 1338
 Celsius, Anders: thermometer intercalibration, 1399
 Chagall, Marc: stained-glass master, 1355
 Chance, George and Edward: printed glass, 1371
 Chaptal, Jean-Antoine: basalt bottles, 1422
 Chevandier, Eugène: dependence of glass properties on cooling rate, 1415

Choniates, Niketas: protective glazing dismounting in 12th-century Byzantium, 1382
 Colbert, Jean-Baptiste: Manufacture royale des glaces, 1372
 Colburn, Irving Wightman: updraw-bending process for flat glass, 70, 1136, 1355
 Colladon, Jean-Daniel: luminous fountain, 705–706
 Copernicus, Nicolaus: *Revolutions of the Heavenly Spheres*, 1390
 Cremer, Max: glass electroconductivity, 610
 Crookes, William: imaging of radiant matter, 789; radiant matter, key to the physics of the universe, 1406–07

D

Dalton, John: atomic theory, 1421
 Danner, Edward: tubing drawing process, 881
 Darduin, Giovanni: Venetian glass recipes, 1328, 1336
 Darwin, Charles: praise of diatoms, 958
 Davy, Humphry: electric arc, 775; discovery of alkali and alkaline earth elements, 1421
 Décorchemont, François: *pâte de verre* stained glass, 1356
 Delaunay Deslandes, Pierre: lime addition needed with pure soda ash, 1420
 Delloye, Lucien: Saint-Gobain mechanical engineer, 1373
 Democritus of Abdera: atomic theory, 609
 Descartes, René: Earth's igneous origin, 1425; description of the glass transition, 1419, 1429; interpretation of annealing, 1419; theoretical refraction law, 1391, 1419
 Diderot, Denis, and D'Alembert, Jean: glassmaking in the *Encyclopédie*, 1364, 1387; marvelous use of glass in chemistry, 1387; Newton's anatomy of light, 1387
 Dietrich of Freiberg: rainbow experiments, 1390
 Dietzel, Adolf: criterium for glass formation, 255; field strength, 1433
 Dollond, John: cancellation of chromatic aberration with concave *flint* and *convex* crown lenses, 1394
 Dollond, Peter: improved cancellation of chromatic aberration, 1394
 Domenicus fiolarius: origins of Venetian glassworking, 1328
 Du Fay, Charles Cisternai: resinous and vitreous electricities, 1404
 Dulong, Pierre-Louis: water vapor pressure measurements up to 30 atm, 1403

Dumas, Jean-Baptiste: crown glass, definite compound, 1424; extended definition of glass, 1414; glass, enabler of chemistry, 1397; systematic analyses of glass compositions, 1423–24
 Duwez, Pol: metallic glasses, 919, 1434

E

Ebelmen, Jacques-Joseph: sol-gel process, 969
 Edison, Thomas: incandescent lamp, 776
 Ehrenberg, Christian Gottfried: phytoliths, 957
 Empedocles of Agrigento: philosophy of matter, 1273; theory of pores, 1275
 Euclid: *Optica*, 705
 Euler, Leonhard: theory of chromatic-aberration cancellation, 1394

F

Fahrenheit, Daniel: thermometer
 intercalibration, 1399
 Faraday, Michael: borosilicates, 867, 1424; glass blower himself, 1399; glass discoloration, 405
 al-Fârîsî: rainbow experiments, 1390
 Fick, Adolf: diffusion laws, 465, 478
 Figuié, Louis; glass and civilization, 2
 Flavius Josephus: ancient glass, 1261
 Formica, Giovanni Odaccio, crystal glass patent, 1338
 Forrest, John H.: early float-process patent for flat glass, 72
 Fourcault, Émile: updraw process for flat glass, 70, 1355
 Fourier, Joseph: heat equation, 48, 487
 Franklin, Benjamin: *glass armonica* musical instrument, 4
 Fraunhofer, Joseph von: achromatic refracting telescope, 1394; antireflection layer on glass, 763; collaboration with Guinand, 1394
 Fuchs, Johann Nepomuk: water glass, 857, 1423
 Fulcher, Gordon S.: electrofused refractories, 1374; VFT viscosity equation, 1431

G

Galen of Pergamon: discoveries of Egyptian artisans, 1274
 Galilei, Galileo: glass *thermoscope*, 1399; lense grinder, 4; telescope observations, 801, 1390–1391
 Gallé, Émile, modern enamels on glass, 1310, 1322; quantum-dot yellow coloration of enamels, 1322
 Gaudin, Marc-Antoine: drawing of SiO₂ glass fibers, 1422

Gay-Lussac, Joseph Louis: isolation of silica, 1414; law of gas-volume combinations, 1421
 Gehlen, Adolph Ferdinand: scientific basis of glassmaking, 1413; sodium sulfate, source of soda, 1413, 1420
 Geissler, Hans: discharge tubes, 1405
 Gelhoff, Georg R.: International Committee on Glass founder, 1219
 Giaque, William F.: residual entropy of glasses, 1428
 Gibbs, Josiah Willard: crystallization theory, 560; phase rule, 529, 1425
 Gibson, George Ernest: heat capacity variations at the glass transition, 1429; residual entropy of glasses, 1428
 Gilbert, William: *electric* phenomena, 1404
 Glauber, Rudolph: *liquor silicum*, 1418
 Gobbe, Émile: updraw process for flat glass, 70
 Gorgias: theory of pores, 1275
 Gray, Stephen: electric conductors and insulators, 1404
 Greig, Joseph W.: liquid immiscibility, 1425
 Griffith, Alan A.: theory of rupture, 1426–27
 Grottus, Theodor von: proton transfer in water, 456
 Grüber, Jacques: decorated glass windows, 1355
 Guinand, Pierre-Louis: glass homogenization process, 1364, 1394, 1395; positive consequences for astronomy, 1408

H

Haber, Fritz: glass electrode, 610
 Haeckel, Ernst: *Die Radiolaren*, 951, 956
 Hales, Stephen: blood pressure, 1404; sap pressure, 1403–1404
 Hall, James: effect of cooling rate on vitrification, 1422
 Harcourt, William Vernon: incorporation of novel elements in glass, 1424
 Harrison, William: English crave for Venetian glass, 1337
 Hartley, James: rolled-glass process, 1370
 Hartsoeker, Nicolaas: poor quality of optical glass, 1391
 Haudicquer de Blancourt, Jean: alchemical roots of glassmaking, 1419; *L'Art de la verrerie*, 1363; malleable glass, 1417
 Hauksbee, Francis: electroluminescence, 775, 776, 1404
 al-Haytham, Abû 'Alî al-Hasan Ibn: *Book of Optics*, 705, 1388–89

Heal, William E.: early float-process patent for flat glass, 72
 Hecataeus of Abdera: Egyptian principle of matter, 1274
 Helmont, Joan Baptista van: chemical recovery of sand from glass, 1419; *soluble silicates*, 857
 Hench, Larry: bioglasses, 991, 1433
 Hero of Alexandria: air dilation in glass vessels, 1399; glass, part of recreational devices, 1395–1396
 Herschel, William: nebulae and star clusters, 801, 1395
 Hitchcock, Halbert K.: early float-process patent for flat glass, 72
 Hittorf, Johann Wilhelm: “melting” of amorphous selenium, 1414
 Holbach, Paul-Henri Thiry, baron d’: Neri’s French translator, 1364
 Homer: *kyanos*, blue glass, 1275
 Hood, Harrison: Vycor, 869; electrofused refractories, 1374
 Hooke, Robert: compound microscope, 1391; *Micrographia*, microscopic observations, 705, 1392–1393; observations of Prince Rupert’s drops, 1420; vacuum pump, 1401
 Houghton, Arthur A.: founder of the Corning Museum of Glass, 1450
 Hutton, James: the Earth as a heat engine, 1422

I

Ingle, Henry W.: Individual Section machine, 81
 Isidore of Seville, saint: glassmaking, 1417; obsidian, 1417

J

Jabir ibn Hayyân: alchemist, 1417
 James I, king of England: *Proclamation touching Glass*, 1366, 1394
 John, saint: Apocalypse, 1279
 Joly, John: pleochroic haloes, 405, 406
 Joong, Ki En: stained-glass master, 1337
 Julius Alexander; Roman glass blower, 1303
 Julius Caesar: gem collector, 1278

K

Kauzmann, Walter: entropy catastrophe, 257, 266, 275, 1431; estimates of glass transition temperatures, 249
 Kepler, Johannes: compound microscope, 1391; internal light reflection, 705
 Klemensiewicz, Zygmunt: glass electrode, 610

Kohlrausch, Eudolph: stretched exponential function, 1431
 Kunckel, Johannes von Löwerstern: Bohemian glass, 1337; gold-ruby glass, 1338; Neri’s German translator, 1363

L

Laplace, Pierre-Simon de: formation of the solar system, 801
 Laurent, Claude: glass flute, 4
 Lavoisier, Antoine-Laurent de: chemical glassware, 1398; *earths*, mistaken for *oxides*, 1421; water attack of glass vessels cause of the apparent transmutation of water into earth, 1397
 Le Chatelier, Henry: lechatelierite (fulgurite), 817; α – β transition of quartz, 1414
 Le Vieil, Pierre: treatise on painting on glass, 1351
 Lebedev, Alexander A.: microcrystalline theory of glass, 1429
 Leblanc, Nicolas: artificial soda ash, 1136, 1420
 Leeuwenhoek, Antoni van: magnifying glass, 1392; microscopic observations, 1392, 1394
 Lehman, Otto: liquid crystals, 793
 Leibniz, Gottfried Wilhelm: igneous origin of the Earth, 1425
 Lémery, Nicolas: acidity theory, 609
 Lewis, Gilbert Newton: residual entropy of glasses, 1428
 Liebig, Justus von: advantages of glass in chemistry, 1397; *Kaliapparatus*, 1399; silver thin films, 763
 Lippershey, Hans: telescope, 1390
 Lomonosov, Mikhail Vasilyevich: extensive glass syntheses, 1423; *Letter on the use of glass*, 4; from glass to the lightning rod, 1408
 Loysel, Pierre: physics applied to glassmaking, 1381, 1413
 Lubbers, John H.: *iron lung* for glassblowing, 67, 68
 Luynes, Victor de: mechanical study of Prince Rupert’s drops, 1425–1426

M

Mackintosh, Charles Rennie: 19th-century stained-glass master, 1355
 Mandeville, Sir John: glassmaking at the pit of Memmon, 1363
 Maquer, Pierre Joseph: glass, outstanding material for chemistry, 1397
 Marcet, Alexander: vitrification of SiO₂, 815, 1422

Marius: glass formation under deep-Earth conditions, 1418

Matisse, Henri: stained-glass master, 1355

Maxwell, J. Clerk: electromagnetism, 665, 705; model of viscoelastic fluids, 1431

Merrett, Christopher: Neri's English translator, 1363

Moore Hall, Chester: correction of chromatic aberration, 1394

Morey, George W.: devitrification, 559; phase-equilibria determinations, 1425

Mozart, Wolfgang Amadeus: *adagio* and *rondo* for the glass armonica, 4

N

Neri, Antonio: *Arte vetraria*, 1137, 1328, 1337, 1362–64

Nernst, Walther: equation for cell e.m.f., 611; glass as a supercooled liquid, 1433

Nero, Roman emperor: fluorite bowl, 1279

Newton, Isaac: chromatic aberration, 1392; light dispersion, 1392; natural philosopher, 1388; nature of light, 1387, 1392; Newtonian liquid, 1431; *Opticks*, 705, 763; sticking of glass panes, 751

Nicol, William: light polarization with calcite prism, 1409

Nobel, Alfred: diatoms and dynamite, 956

Northumberland, Duke of: glazing dismounting before storms, 1381

O

Obsius: obsidian, 1236

Ørsted, Christian: electromagnetism, 1405

Ostwald, Wilhelm: ripening, 970; step rule, 563

Owens, Michael J.: suction machine for bottles, 1378–79

P

Pascal, Blaise: barometric experiments, 1401; hydraulic press, 1400–1402; hydrostatic pressure, 1400; refutation of *horror vacui*, 1400; weight of the atmosphere, 1401

Paxton, Joseph: design of the London Crystal Palace, 1371

Peiler, Karl E.: press-and-blow machine, 81, 1380

Péligot, Eugène: Glass treatise, 1364

Pelouze, Théophile-Jules: devitrification mechanisms, 1422

Perrot, Bernard: gold-ruby glass, 1338; Saint-Gobain plate-glass process, 1372

Perskyi, Constantin: television, 789

Petronius Arbitrator: glass not smelling, 3: malleable glass, 1417

Petrov, Vassili Vladimirovich: electric arc, 725

Philip August, king of France: paving of Parisian streets, 1191

Philo of Byzantium: air dilation in glass vessels, 1399; glass in mechanical devices, 1395

Picard, Jean: electroluminescence, 1404

Pilkington, Sir L.A.B. (Alastair): float process for flat glass 72, 1375

Plato of Athens: element polyhedra, 128, 1276; glass, mixture of water and earth particles, 1276; *hyalos*, glass, 1275; metals, defined by their mining, 1275; philosophy of matter, 1273

Pliny the Elder: *ammonitrum*, 1417; *caeruleum*, blue pigment, 1275; doubts about flexible glass, 1232, 1236; gem counterfeiting, 1278, 1279, 1280; glass coloration in secondary workshops, 1287; gold, less expensive than gems, 1280; invention of glass, 1232, 1235–36, 1277, obsidian, 1236, 1237, 1261; rock crystal, 1279; sympathy and antipathy, 1280

Polinière, Pierre: electroluminescence, 775, 776, 1404

Pompeius Magnus: gem collector, 1278

Prout, Joseph: law of definite proportions, 1421

Prudentius: early Byzantine praise of stained glass, 1341

Psellos, Michael: metal transmutations, 1281

Pseudo-Democritus: alchemist, 1278, 1281

Ptolemy, Claudius: refraction experiments, 1388–1389; *Optica*, 705

Pugin, Augustus and Charles: 19th-century stained glass masters

R

Ravenscroft, George: *flint*, crystal glass, 1337, 1338, 1364, 1394

Réaumur, René-Antoine Ferchault de: partial melting of porcelains, 1422; Réaumur's porcelain, 937, 1422–1423; thermometer intercalibration, 1399

Reinitzer, Friedrich: liquid crystals, 793

Röntgen, Wilhelm: X-rays, 788, 1406

Rosing, Boris: *electric telescope*, 789

Rouelle, Guillaume-François, *base*, forming a salt with an acid, 609

Rupert of the Rhine, prince: *lacrymae batavicae*, 1420

Rutherford, Ernest: pleochroic-halo dating, 403

S

Sabellico, Marco Antonio: gem imitation with glass, 1335
 Sanchez-Vello, Leopoldo : tubing drawing process, 881
 Saussure, Théodore de: silica in plant ashes, 957
 Schott, Otto: properties of novel optical glasses, 867, 1424
 Seger, Hermann, checking reference cones for ceramic firing conditions, 1313; thermal-expansion predictions for ceramics, 1312
 Séguy, Gaston: early diversity of X-ray tubes, 1407
 Seneca: confusion of Bolus of Mendes with Democritus, 1378; distorted vision through glass, 1388; light dispersion by a glass prism, 1392; mineral transformations, 1279
 Sentia Secunda: Roman glass blower, 1303
 Siemens, Carl Wilhelm (William) and Friedrich (Frederick), 1367: production of water gas, 1367–1368; radiative furnaces, 1368; regenerative furnace, 1367; regenerative tank furnace, 1368–1369; tempered glass, 1092, 1426
 Simon, Franz: configurational properties, 1430
 Sloane, Sir Hans: founder of the British Museum, 1441
 Smith, F. Goodwin: Individual Section machine, 81; press-and-blow machine, 81
 Snellius, Willebrod: internal reflection, 705; law of refraction, 1391
 Sorby, Henry Clifton: petrographic microscope, 1409
 Sørensen, Søren P.L.: pH definition, 609
 Spallanzani, Lazzaro: confusion between heat and temperature, 1399
 Sparks, George S.: glass as a fifth state of matter, 1429
 Spinoza, Baruch: lense grinder, 4
 Stephanos of Alexandria: alchemist, 1281
 Stevels, Johannes Marinus: NBO/T ratio, 1433
 Stirling, Robert: heat *economizer*, 1367
 Stokes, George Gabriel: optical investigations of Harcourt's glasses, 1424
 Stoney, George: coining of “electron,” 1406
 Stookey, S. Donald: glass-ceramics, 938, 947, 1009
 Strabo of Amaseia: ancient glassmaking, 1261
 Strass, Georges Frédéric: *rhinestone* jewelry, 4
 Struve, Gustav Adolf: phytoliths, 957
 Suárez-Núñez, Miguel Jerónimo: Neri's Spanish translator, 1364
 Suger, abbot of St-Denis: stained glass, 1347

T

Takayanagi, Kenjiro: image broadcasting, 789
 Tammann, Gustav: crystal nucleation and growth, 937, 1423; glass as a supercooled melt, 1423; VFT viscosity equation, 1431
 Thénard, Louis Jacques: definition of glass, 1414; isolation of silica, 1414
 Theophilus presbyter: ashes selected for glassmaking, 1356; cylinder process for flat glass, 1344; glass coloration, 1344; glassmaking, 1362, 1418
 Theophrastus of Eresus: definition of glass, 1414; glass coloration, 1415; imitation of nature, 1277; melting of obsidian, 1416–17; slag formation, 1416
 Thévenot, Melchisédech: bubble level, 1397
 Thölde, Johann: attack of glass by soda and potash, 1418
 Thomson, Joseph John: electron, 789, 1408
 Thomson, William, Lord Kelvin of Largs: measurements of thermal properties, 313, 1425; natural philosopher, 1388
 Tiffany, Louis Comfort: coloring innovations, 1355
 Tool, Arthur Q.: attainment of equilibrium state, 1428; fictive temperature, 1430; heat effects of the glass transition, 1427
 Torricelli, Evangelista: air pressure from experiments with glass tubes, 1400
 Turner, William E.S.: ICG founder, 1219; pioneer of ancient-glass studies, 1251

V

Valentinius, Basilius: pen name of Johann Thölde, 1418
 Varro, Caius Terentius: glass akin to emerald, 1279
 Vinci, Leonardo da: eyeglass machining, 4
 Vogel, Hans : VFT viscosity equation, 1431
 Volta, Alessandro: electric pile, 1405, 1421

W

Warburg, Emil: ionic conduction in glasses, 453
 Warren, Bertram E.: bridging and nonbridging oxygens, 1432; continuous random network, 130; origin of liquid immiscibility, 1432; radial distribution functions, 1431
 Wertheim, Guillaume: dependence of glass properties on cooling rate, 1415
 Whevell, William: coining of *dielectrics*, 1405; *scientist*, 1388
 White, Walter P.: calorimetric glass transition, 1427; glass transition, 1429

Woods, William: blowing machine for electrical bulbs, 778

Y

Yablochkov, Pavel: electric-arc *candle*, 776

Young, Thomas: index of refraction, 1391

Z

Zachariasen, William H.: continuous random network, 130, 1432

Zosimos of Panopolis: alchemist, 1281; alchemical glassware, 1282, 1396
